Alkali feldspars can be replaced completely or partially by leucite (Section 2.3), nepheline or nepheline syenite (Section 2.2), thereby increasing the alkali oxide and Al_2O_3 content and reducing the SiO_2 content. If low levels of accompanying minerals and heavy metal ions are unnecessary, other substitutes can be used: feldspathic pegmatites, aplites, phonolites and porphyries; and to a limited extent plagioclase, anorthosite (plutonic rocks containing ca. 90 % plagioclases), Cornish stone (though this can liberate fluorine on thermal decomposition of the melts) and the blast furnace slags "Carolina stone" and "Calumite" (both consisting of kaolinite, feldspar, quartz and some fluorspar).

Worldwide extraction of feldspars is estimated at $> 6.7 \times 10^6$ t/a. Together with nepheline, nepheline syenite, and leucite, total production exceeds 7.5×10^6 t. In 1990, 247 000 t feldspar and 135 000 t pegmatite were produced in the Federal Republic of Germany.

The production figures of pegmatite in 1988 – 1993 in the United States are ca. 670 000 t/a, in the CIS 310 000 t/a, in Italy ca. 295 000 t/a, in France ca. 195 000 t/a, in Mexico ca. 127 000 t/a, in Brazil ca. 110 000 t/a, in Spain ca. 90 000 t/a, in Turkey ca. 73 000 t/a, in Norway ca. 71 000 t/a, in Venezuela ca. 70 000 t/a, in Finland ca. 68 000 t/a, in Rumania ca. 60 000 t/a, in Sweden ca. 52 000 t/a, in India ca. 50 000 t/a, in Argentina and in the Republic of South Africa ca. 47 000 t/a, respectively.

The total feldspar mining production in 1994 amounted to 1 806 935 t in Italy, 765 202 t in the United States, 528 027 t in Thailand, 500 000 in Turkey, 385 000 t in France, 379 427 t in Ger-

many, 319 658 t in South Korea, 274 789 t in Venezuela, 250 000 t in Spain, 170 000 t in the Czech Republic, 140 000 t in Brazil, 133 400 t in Mexico, 92 440 t in Portugal, 79 000 in Iran, 76 188 t in Colombia, 70 000 t in Russia, 70 000 t in India, 62 905 t in Norway, 55 000 t in Sweden, 53 503 t in Japan, 50 000 in Argentina, 46 000 t in Poland, 43 805 t in the Philippines, 43 600 t in Hungary, 41 389 t in Finland, 40 000 t in Cuba, 39 745 t in Egypt, 37 156 t in the Republic of South Africa, and 35 000 t in Greece. Furthermore, the feldspar mining production amounted in 1994 e.g., to 23 500 t in Australia, to 8000 t in the United Kingdom, and 4883 t in Austria.

2.2. Nepheline and Related Compounds

The alkali aluminosilicate nepheline, $KNa_3[AlSiO_4]_4$, a feldspathoid, belongs to the nepheline group of tectosilicates without nontetrahedral anions. The aluminum : silicon ratio is 1 : 1.

Structure and Mineralogy. As in all tectosilicates, the oxygen ions at the vertices of the $[AlO_4]$ and $[SiO_4]$ tetrahedra in nepheline are linked to the four neighboring tetrahedra. This produces a three-dimensional open framework in which the relatively large Na^+ and K^+ cations are located in the spaces between the tetrahedra. In tectosilicates, these spaces can be occupied by alkaline-earth ions, nontetrahedral anions (e.g., in the feldspathoids sodalite and scapolite), or water (in zeolites). In minerals of the nepheline group the tetrahedra exhibit a hexagonal or pseudohexagonal arrangement. In nepheline (Fig. 22), alternating $[AlO_4]$ and $[SiO_4]$ tetrahedra are linked together at common vertices to form an easily distorted high-tridymite structure with six-membered rings. The apices of the $[AlO_4]$ tetrahedra point parallel to the *c* axis, and those of the $[SiO_4]$ tetrahedra point in the opposite direction. Unlike the high-tridymite structure, Si^{4+} ions in nepheline are replaced by Al^{3+} ions in half of the tetrahedral positions. In order to maintain charge neutrality, 3 Na^+ ions and 1 K^+ ion are found per formula unit in the centers of the channels parallel to the *c* axis.

Figure 22. Idealized structure of nepheline, $KNa_3[AlSiO_4]_4$, with $[(Si, Al)O_4]$ tetrahedra linked to form six-membered rings
Projection parallel to *c* on (001)

In natural nepheline, the ratio of K^+ to Na^+ can vary considerably, and Ca^{2+} can also be incorporated in the lattice. There is often an excess of SiO_2, i.e., less than half the Si^{4+} is replaced by Al^{3+}, so that less Na^+ is required to maintain charge neutrality.

Nepheline [*012251-27-3*], $KNa_3[AlSiO_4]_4$, crystallizes in the hexagonal – pyramidal system with space group $C_6^6 - P\,6_3$ and has the following lattice constants: $a_0 = 1.001$ nm, $c_0 = 0.841$ nm; the axial ratio is $c_0/a_0 = 0.840$; $Z = 2$. $\varrho = 2.65$ g/cm^3 (also potassium-free with $a_0 = 0.996$ nm, $c_0 = 0.836$ nm).

The following minerals of the nepheline group have properties similar to those of nepheline:

Kalsilite, $K[AlSiO_4]$ (Fig. 23), crystallizes in the hexagonal – pyramidal system with space group $D_6^6 - P\,6_3$; lattice constants: $a_0 = 0.518$ nm, $c_0 = 0.869$ nm; the axial ratio is $c_0/a_0 = 1.678$; $Z = 2$.

Trikalsilite, $(Na, K)[AlSiO_4]$, crystallizes in the hexagonal system, probably with space group $C_6^6 - P\,6_3$; lattice constants: $a_0 = 1.54$ nm, $c_0 = 0.86$ nm; the axial ratio is $c_0/a_0 = 0.559$; $Z = 18$.

Kaliophilite, $K[AlSiO_4]$, crystallizes in the hexagonal – trapezohedral system with space group $D_6^6 - P\,6_3 22$; lattice constants: $a_0 = 2.706$ nm, $c_0 = 0.861$ nm; the axial ratio is $c_0/a_0 = 0.318$; $Z = 54$; pseudocell: $a_0' = 1.562$ nm $= a_0/3$, $c_0 = 0.861$ nm, $c_0/a_0 = 0.551$; $Z = 18$.

Figure 23. Structure of kalsilite, $K[AlSiO_4]$. The structure of nepheline, $KNa_3[AlSiO_4]_4$, is obtained by replacement of K_4 by KNa_3

High eucryptite, $Li[AlSiO_4]$, only exists as a synthetic product, and is obtained by heating natural eucryptite (low eucryptite), $LiAl[SiO_4]$; it is stable above 962 °C. It crystallizes in the hexagonal – trapezohedral system with a superlattice structure, with space group $D_6^4 - P\,6_222$ or $D_6^5 - P\,6_422$; lattice constants: $a_0 = 0.528$ nm, $c_0 = 1.127$ nm; the axial ratio is $c_0/a_0 = 2.134$; $Z = 3$.

Nepheline is a feldspathoid and occurs only in rocks with a low SiO_2 content (< 50 wt % SiO_2); it has a lower SiO_2 content than the alkali feldspars. It is formed in alkaline rocks in place of albite if the magma is sufficiently unsaturated with SiO_2. It is often associated with other feldspathoids such as sodalite, cancrinite, or leucite, or less often with kalsilite. Nepheline is a typical main constituent of the Atlantic-type igneous rocks, plutonic rocks (e.g., foyaites, theralites and essexites), hypabyssal and volcanic rocks (e.g., phonolites, tephrites and nephelinites). In the Mediterranean suite, minor amounts of nepheline are usually found with the common leucite (see Section 2.3). Nepheline crystallizes immediately after mafic minerals in magmatic rocks, and at about the same time as alkali feldspars in plutonic rocks. In hypabyssal and effusive rocks, nepheline occurs as phenocryst and in the matrix.

The ratio potassium : (potassium + sodium) in nepheline varies between 7 % and 37 % in effusive rocks and also in plutonic rocks, in which nepheline was formed in the presence of anorthoclase or sanidine. In plutonic rocks containing orthoclase and albite, nepheline contains 14 – 23 atom % potassium. Igneous nepheline (slow cooling) has a cloudy or greasy luster and is known as elaeolite. On rapid cooling (effusive rock), the crystals remain clear. Albite can form isomorphous mixtures with nepheline in sodium-rich solid solutions with a maximum albite content of ca. 20 mol % at 700 °C; the albite is often irregularly distributed, i.e., in zones. As with feldspar (see Section 2.1.2), the order/disorder behavior of Al/Si in the nepheline is temperature dependent.

Occurrence in Industrial Products. In refractory technology nepheline occurs in four modifications that do not contain potassium, $NaAlSiO_4$:

High carnegieite [*001302-34-7*], α-$Na[AlSiO_4]$, crystallizes in the cubic system, with space group $T^4 - P\,2_13$; lattice constants: a_0 = ca. 0.74 nm, $Z = 4$. It has the cubic high cristobalite-type lattice with additional sodium, and can form mixed crystals with cristobalite to a limited extent. High carnegieite occurs only as a synthetic product; in mineralogy it is often termed *β-carnegieite.*

High nepheline [*012251-27-3*], β-$Na[AlSiO_4]$, is orthorhombic. *Low nepheline* [*012251-27-3*], γ-$Na[AlSiO_4]$, is hexagonal – pyramidal. It occurs, for example, in chamotte and SiO_2- containing corundum bricks. It is converted into mullite in the walls of blast furnaces, glass-melting furnaces and checker bricks by the attack of Na_2SO_4 and Na_2O. *Low carnegieite,* β-$Na[AlSiO_4]$, is triclinic.

In refractory technology, five modifications of the polymorphic substance $KAlSiO_4$ are known: hexagonal – trapezohedric kalsilite, orthorhombic (high) kaliophilite, hexagonal kaliophilite (kalinepheline), natural hexagonal kaliophilite and anomalous kaliophilite. A characteristic feature of kalsilite is that it "polymerizes": trikalsilite and tetrakalsilite are known.

Kalsilite occurs in incrustations on the chamotte walls of blast furnaces and in the chamotte checker bricks of Siemens – Martin furnaces. *Potassium – nepheline* is formed at $< 1540\,°C$ in chamotte bricks of industrial furnaces that are exposed to K_2O vapors (e.g., in the brick linings of blast furnaces and tuyeres). *High kaliophilite* is stable above 1540 °C. It also occurs in the chamotte linings of blast furnaces and tuyeres, as well as in the chamotte checker bricks in Siemens – Martin furnaces and glass furnaces used to melt optical K_2O glasses.

Properties and Composition of Industrial Products. The following physical properties are important for industrial applications.

Density:
Nepheline: 2.56 – 2.665 g/cm^3
Kalsilite: 2.59 – 2.625 g/cm^3
β-Carnegieite: 2.513 g/cm^3
α-Carnegieite: 2.343 g/cm^3

Mohs hardness:
Nepheline: 5 1/2 – 6
Kalsilite: 6

Specific heat at 20 – 100 °C:
Crystalline: 0.77 J g^{-1} K^{-1}
Amorphous glass: 0.804 J g^{-1} K^{-1}

Melting point:
Sodium nepheline + albite, 100 – 70 % $NaAlSiO_4$: 1526 – 1410 °C
Kalsilite (0 – 20 % $NaAlSiO_4$): 1300 – 1350 °C
β-Carnegieite (ca. 100 % $NaAlSiO_4$): 1526 °C
Eutectic in the system nepheline – albite: 1068 °C

Transformation temperature:
Nepheline $\rightarrow \alpha$- carnegieite: 1248 ± 5 °C
α-Carnegieite $\rightarrow \beta$- carnegieite: 687 – 692 °C
Nepheline + 30 % kalsilite $\rightarrow \alpha$- carnegieite: 1400 °C
Nepheline + 35 % anorthite $\rightarrow \alpha$- carnegieite: 900 °C

Nepheline shows piezoelectric properties in a high-frequency field.

Compositions of commercially mined nephelines are given in Table 7.

Nepheline has a markedly alkaline reaction in water. Dilute acids, especially HCl, decompose nepheline, producing gelatinous silicic acid.

Deposits. Only a small number of workable nepheline syenite deposits are known, the most important of which are in Canada, Norway and Russia. The rock in a certain Canadian deposit consists of ca. 54 % albite, 18 % microcline, 18 % nepheline, < 4 % biotite, 6 % muscovite and magnetite. In the Western world, only four companies extract and process nepheline-containing rocks (only nepheline syenite), the combined output being ca. 1.2×10^6 t/a.

Extraction. The rock is usually extracted by open- cast mining using explosives. Adhering impurities are removed by sieve grates (grizzlies) prior to size reduction. Ferromagnetic impurities (e.g., biotite) are removed by means of rotary magnets or high-intensity magnetic separation.

Quality Specifications. The quality required depends on the use, e.g., Grade A (Table 8) for the glass industry, Grade B for glass wool manufacture, ceramic grade for the ceramic industry and a lower grade for use as a filler. The grades differ in iron content (Grade A ≤ 0.08 % Fe_2O_3, Grade B: ≤ 0.4 % Fe_2O_3) and in color, which varies with heavy metal content and mean particle size (in some applications).

Uses. The most important consumer is the *glass industry,* which accounts for ca. 70 % of the nepheline marketed. Here, the silicate acts not only as a source of SiO_2 and Al_2O_3, but also as a flux. Mixtures of raw materials for bottle manufacture can contain 5 – 15 % nepheline. Nepheline can replace feldspars in most ceramic and glass-making applications (see Section 2.1.7) with only small adjustments to batch chemistry being necessary. The choice between feldspar and nepheline (nepheline syenite) is often a question of cost.

The *ceramic industry* consumes ca. 15 % of the total nepheline output. The nepheline content in sanitary and whiteware ceramics can be

Finely ground nepheline and feldspar (see Section 2.1.7) are becoming increasingly important as *fillers* for plastics [especially unsaturated polyester resins, poly(methyl methacrylate), and thermoplastic polyurethanes], rubber, adhesives, paints and pigments (Table 9). Since the refractive indices of nepheline and the matrix are almost the same, e.g., in nepheline/poly(vinyl chloride) compositions, transparency is maintained, even at high pigment volume concentrations. The high surface and volume resistance of nepheline mean that it can also be used as a filler in insulating paints, casting resins for electrical applications and other products.

In Russia, nepheline syenite is an important raw material for *aluminum production.* In a multistage process, the Al_2O_3 is extracted and then treated by melt electrolysis. High activity *silica gels* can be produced from nepheline by decomposition with hot 22 % sulfuric acid.

2.3. Leucite

The potassium aluminum silicate leucite, a feldspathoid, belongs to the analcime – leucite group of tectosilicates without nontetrahedral anions. The aluminum : silicon ratio is 1 : 2.

Structure and Mineralogy. As with all the tectosilicates, the oxygen ions at the vertices of the $[AlO_4]$ and $[SiO_4]$ tetrahedra are linked to four neighboring tetrahedra. This produces a three-dimensional open framework in which K^+ ions are located in the spaces within the framework. Whereas in the nepheline group the arrangement of tetrahedra is hexagonal or pseudohexagonal, the minerals of the analcime – leucite group have a cubic or pseudocubic arrangement.

Leucite [*001302-34-7*], $K[AlSi_2O_6]$, is dimorphous. Below 605 °C, it exists as low leucite (α-leucite) and above 605 °C as high leucite (β-leucite). *Low leucite* crystallizes in the tetragonal – pseudocubic system, with the space group C^6_{4h} – $I4_1/a$; lattice constants: $a_0 = 1.304$ nm,

Table 9. Physical data for nepheline fillers

Product∗	Particle diameter, µm		Brightness	Density,
	D_{50} value	Upper limit	(555 nm)	g/cm^3
Minex 4	10.8	30	90	2.6
Apex 400	9.1	32	90.5	2.6
Minex 7	3.9	20	90	2.6
Apex 700	5.9	25	92	2.6
Minex 10	2.7	15	90	2.6

∗ Trade names: Minex is produced by Indusmin and Apex by IMC.

$c_0 = 1.385$ nm; the axial ratio is $c_0/a_0 = 1.062$; $Z = 16$. *High leucite* crystallizes in the cubic – hexakis-octrahedral system, with the space group O_h^{10} – Ia 3 d; $a_0 = 1.343$ nm; $Z = 16$.

Leucite is isotypical with analcime, $Na[AlSi_2O_6] \cdot H_2O$; pollucite, $(Cs, Na)[AlSi_2O_6] \cdot H_2O$, and synthetic $Cs[FeSi_2O_6]$; it is homeotypic with wairakite, $Ca[AlSi_2O_6]_2 \cdot H_2O$. In leucite, K^+ can be replaced to a small extent by Na^+, rarely by Rb^+, and very rarely by Ca^{2+}; these minor substituents sometimes appear as enriched isomorphous layers. The pseudocubic, pale green iron(III) leucite, $K[FeSi_2O_6]$, also known as a synthetic material, can occur in very small quantities with the rock-forming leucite.

The apparently cubic crystals of leucite are anisotropic and consist of numerous twin lamellae, which are arranged parallel to the surfaces of the apparent rhombic dodecahedron. In thin sections, leucite shows a complex twinning on {110} under crossed polarizers. On raising the temperature to 605 °C, leucite becomes isotropic and is then genuinely cubic (high leucite). The transformation is reversible.

Leucite is the most characteristic component of SiO_2-unsaturated magmatites with a preponderance of potassium (Mediterranean rocks) and is typical of magmatic regions (e.g., the Rome region in Central Italy). It is found in many foyaitic and theralitic volcanic rocks.

Leucite occurs in refractory products, e.g., in chamotte bricks from blast furnaces and tuyeres.

High leucite melts congruently at 1686 °C. When potassium feldspar is heated, it melts incongruently above 1150 °C forming a mixture of leucite crystals in a SiO_2-rich melt. At 1150 °C, the melt contains 57.8 wt % leucite crystals, and at 1530 °C all the leucite becomes molten. On cooling, leucite crystallizes first, and the melt therefore becomes richer in SiO_2. The leucite crystallization is completed at 1150 °C and potassium feldspar is then formed.

Properties. Leucite crystals are usually white or gray, glassy, translucent, but very seldom clear. Cleavage is poor parallel to (110), the fracture being conchoidal and brittle. The following physical properties are important for the use of leucite as a raw material for glass:

Density: leucite 2.47 – 2.50 g/cm^3, molten glass produced from leucite 2.41 g/cm^3.

Mohs hardness: 5 1/2 – 6.

Melting point: pure leucite 1686 °C, impure leucite 1298 – 1430 °C.

Heat of crystallization: 47.65 kJ/mol. The tendency to crystallize is very low, and the melt therefore usually solidifies as a glass. Volume increase on solidification of the melt: 2.9 %.

Specific heat (10 – 100 °C): natural mineral 0.8 J g^{-1} K^{-1}, in the amorphous state 0.733 J g^{-1} K^{-1}.

Leucite can contain up to 1.5 wt % Na_2O and 0.8 wt % CaO. It is decomposed by concentrated hydrochloric acid with precipitation of SiO_2.

Deposits and Processing. Leucite deposits occur in the United States (Montana and Wyoming) and in Italy (Mount Vesuvius). Processing and classification of the leucite grades are very similar to that of feldspar and nepheline (see Sections 2.1.6 and 2.2).

Uses. Leucite, like feldspar, is mainly used as a raw material in glass manufacture. Other applications include the production of potassium fertilizers, alum and potassium nitrate.

2.4. Olivine

Olivine (peridot, chrysolite) [*1317-71-1*] is a rock-forming nesosilicate (an orthosilicate, i.e.,

a silicate with isolated $[SiO_4]^{4-}$ tetrahedra held together by metallic ions) belonging to the olivine series of minerals $(Mg, Fe)_2[SiO_4]$. There is an infinite series of solid solutions of the end members forsterite (Fo) [*015118-03-3*], $Mg_2[SiO_4]$, and fayalite (Fa), $Fe_2[SiO_4]$. The intermediate members are olivine $(Mg_{90-70}, Fe_{10-30})_2[SiO_4]$, hyalosiderite $(Mg_{70-50}, Fe_{30-50})_2[SiO_4]$, hortonolite $(Mg_{50-30}, Fe_{50-70})_2[SiO_4]$, and ferrohortonolite $(Mg_{30-10}, Fe_{70-90})_2[SiO_4]$. Other members of the olivine series include tephroite $Mn_2[SiO_4]$, knebelite, $(Mn, Fe)_2[SiO_4]$, and iron knebelite $(Fe, Mn)_2[SiO_4]$.

Figure 24. Structure of olivine, projection parallel to *b* on (010)
The $[SiO_4]^{4-}$ tetrahedra point alternately upward and downward

Structure and Mineralogy. The minerals of the olivine series form orthorhombic crystals, space group D_{2h}^{16} – Pmcn, $Z = 4$, with the following lattice constants (in nm):

	Forsterite	Olivine	Hortonolite	Fayalite
a_0	0.600	0.601	0.607	0.617
b_0	0.478	0.478	0.479	0.481
c_0	1.028	1.030	1.034	1.061

Olivine (Fig. 24) can include small amounts of other substituent elements (e.g., nickel). Weathering removes MgO and SiO_2, forming the important nickel serpentine ore mineral garnierite (nickel deposits of the New Caledonia type).

Olivine occurs as intergrown, loose, prismatic or thick tabular crystals and as granular aggregates. Cleavage in the (001) plane is good, and also takes place imperfectly in the (010) plane, the fracture being conchoidal.

Olivine crystallizes at an early stage from a magma. It is found typically as the main mineral constituent in ultrabasic igneous rocks (peridotites and dunites), and as a residual material in the serpentinites formed from them. In the ultrabasics, olivine is accompanied by pyroxene, etc. Olivine is often found in basic magmatites both in plutonic and volcanic rocks (e.g., gabbros, diabases, basalts and melaphyres). It also occurs in meteorites. Olivine is a main constituent of the upper earth mantle.

Olivine of jewelry quality is known as chrysolite, and forms clear, pale green stones that can be polished.

In the presence of water, olivine readily forms other silicates, e.g., serpentine (serpentinization – antigorite, chrysotile). Olivine often then becomes pseudomorphosed to form serpentine, $Mg_6[(OH)_8/Si_4O_{10}]$, and talc, $Mg_3[(OH)_2/Si_4O_{10}]$. The magnesium removed during serpentinization occurs as brucite, $Mg(OH)_2$, magnesite, $MgCO_3$, and cryptocrystalline magnesite of the Kraubath type (Styria, Austria). The iron present in olivine forms secondary magnetite Fe_3O_4 $[Fe^{3+}(Fe^{2+}Fe^{3+})O_4]$ during serpentinization.

Synthesis. Synthetic olivine is produced by calcination of chrysotile tailings from the asbestos mines in the Thetford Mines area of Canada. The tailings are calcined at 850 °C in a rotary kiln to give a mixture of forsterite and silica. A purer forsterite can be synthesized by adding magnesite during calcination. The pelletization of magnesite and the tailings is followed by calcination in a rotary kiln at 800 °C and further heating to a temperature of 1350 °C in a static furnace, whereby magnesite combines with the silica to form forsterite.

Forsterite in Industrial Products. Forsterite is a common component of refractory magnesia products (especially chrome–magnesite bricks), and is the principal component of refractory forsterite bricks (→ Glass, Chap. 5.7.). It is used in high-frequency insulators and also occurs in special metallurgical slags and upon reaction of refractory magnesia products with acidic slags.

Properties. Olivine has a glassy luster and is transparent or translucent, but seldom colorless (i.e., iron-free). The yellowish to green color (which gives it its name) varies from light to dark and may be opaque or even black with high iron content. The double refraction (birefringence) indices are usually high and depend on the magnesium : iron ratio.

The following physical properties are important for industrial applications:

Density: forsterite (Fo) 3.21 g/cm^3, Fo_{90}/Fa_{10} (90 mol Fo/10 mol Fa) 3.25 g/cm^3, fayalite (Fa) 4.34 g/cm^3.

Mohs hardness: forsterite 6 1/2 – 7, fayalite 6 1/2.

Melting point: forsterite (no decomposition) 1885 °C (volume change 3 %), fayalite 1205 °C.

Temperature stability limit for magnesium-rich olivine in an oxidizing atmosphere 1750 °C; softening temperature under a load of 2 kg/cm^2 1600 – 1700 °C; thermal shock resistance moderate.

Heat of fusion of forsterite 3.444 kJ/mol; specific heat (21 – 51 °C) 0.791 kJ/g; thermal conductivity (kJ m^{-1} h^{-1} K^{-1}) at 100 °C 19.3, at 500 °C 11.3, and at 1000 °C 8.8; mean coefficient of thermal expansion over the range 0 – 500 °C 8.3×10^{-6} K^{-1}, 0 – 1000 °C 9.5×10^{-6} K^{-1}, 0 – 1500 °C 11.0×10^{-6} K^{-1}.

Free energy of formation: forsterite − 1922 kJ/mol, fayalite − 1337.5 kJ/mol.

Electrical resistivity: at 800 °C 2×10^6 Ω · cm, at 1200 °C 10^4 Ω · cm, at 1400 °C 10^3 Ω · cm.

Ideal chemical compositions: forsterite ($2\,MgO \cdot SiO_2$): 57.3 wt % MgO, 42.7 wt % SiO_2; fayalite ($2\,FeO \cdot SiO_2$): 70.5 wt % FeO, 29.5 wt % SiO_2.

Olivine is insoluble in water, even at elevated temperature and pressure (620 °C, 30.4 MPa). It is stable towards cold acid, but complete decomposition takes place on heating in dilute acid (0.2 mol/L HCl), forming silica gel. Olivine reacts similarly with HNO_3 and H_2SO_4, but dissolves only slowly in 20 % H_2F_2. Solutions of the alkali metal sulfates readily decompose it. Olivine is resistant to alkaline solutions.

The chemical resistance of olivine in refractory materials is good towards reducing atmospheres, moderate toward carbon, poor toward acidic flux, good toward basic flux, and good toward molten metals.

The following data are characteristic of commercial olivines:

Density: 3.1 – 3.3 g/cm^3
Bulk density (dry sand): 1.4 – 1.7 g/cm^3
Tamped density (dry sand): 1.7 – 1.9 g/cm^3
Bulk density (molding sand): 1.7 – 2.1 g/cm^3
Moisture content (max.): 0.5 %
Softening point: > 1700 °C
Specific heat: 0.84 – 1.38 J g^{-1} K^{-1}
Coefficient of thermal expansion (20 – 1200 °C): 11.6×10^{-6} K^{-1}
FeO content (max.): 8 wt %
pH: 9

The most useful properties of forsterite-rich olivines are their high softening point, low and nearly linear thermal expansion, low thermal conductivity, high density, low abrasivity and (unlike silica) lack of toxicity.

Deposits and Commercial Products. An important economic factor in the extraction of olivine is the fact that olivine-rich ultrabasics or olivine rocks and the serpentinites derived from them are associated with chromite, platinum, and nickel deposits. The principal olivine deposits extracted today are in Norway, Japan, Austria, the United States, Italy, Spain and Pakistan. Smaller producers are Mexico, Sweden, India and Brazil. Japan has a large production of olivine and a production of serpentine which is several times higer than that of olivine. [6]t. The first deposit was extracted in 1948 in Aaheim (Norway).

World production of forsterite-rich olivine and dunite is ca. 6.8×10^6 t/a, of which ca. 2.1×10^6 t/a are in Europe.

Commercial olivines usually contain at least 85 % forsterite. Their chemical composition is MgO ca. 45 – 50 %, SiO_2 ca. 40 – 43 %, FeO ca. 5 – 7 %. Loss on ignition is ca. 1 – 2 %.

Rocks that contain higher proportions of derived minerals such as serpentine and talc are known as dunite. The chemical composition is MgO ca. 36 – 42 %, SiO_2 ca. 36 – 39 %, with a correspondingly higher loss on ignition.

Extraction and Processing. Olivine is extracted by both open- cast and underground mining. The rock is usually broken up by explosives.

The mined rock is processed by multistage size reduction (jaw crushers, cone crushers, and hammer mills), and classified by multiple-deck vibratory screens, with intermediate washing to remove any soft accompanying minerals (e.g., pyroxene, serpentine, chlorite or talc) in the form of a slurry. After washing, the material is mechanically dewatered by continuous centrifuges and dried by rotary or belt dryers (residual moisture content < 0.5 %).

Powdered olivine is produced by impact or hammer mills, giving products with narrow particle size ranges and low dust contents.

Uses. Important uses for magnesium-rich olivines are:

1) *Ore additive* in steel blast furnaces to condition the slag and improve its flow. Here, olivine replaces dolomite and silica and enables the ratio $(CaO + MgO) : (SiO_2 + Al_2O_3)$ to be adjusted to ca. 0.8 – 1.2 %. Also, less heat is required to melt the slag components.
2) Olivine is well suited for the *slag conditioning* of furnace slag and for basicity control in blast and electric arc furnaces. Olivine is added in the form of lumps (10 – 40 mm), sinter (3 – 6 mm) and pellets.
3) Olivine sand is used in *foundry sands* for casting manganese steel, high-alloy steels, brass, bronze and aluminum and in the production of gray iron and alloy steel, which usually require a fine finish. Olivine sands have several advantages over silica sands: the casting surfaces are smoother, fettling and cleaning are easier. Olivine sands can be reused many times, and there is no danger of silicosis. However, the basicity of olivine prevents its use in many applications, for example, with acid-catalyzed furan and phenolic no-bake binders.
4) *Highly refractory forsterite bricks* containing magnesia binders and possibly chrome ore (→ Glass, Chap. 5.7.). The added MgO combines with excess SiO_2 to form forsterite. The addition of chrome ore improves thermal shock resistance and reduces the modulus of distortion (V modulus). The most important advantage compared with magnesia bricks is that scale and slags with a high iron oxide content do not adhere to the wall surfaces below 1400 °C because the MgO is bonded. Also, forsterite bricks are less liable to sulfate attack in the temperature range 800 – 1100 °C. However, olivine can be attacked by Al_2O_3, CaO, SiO_2 and alkali due to the formation of lower melting eutectics. For refractory-grade olivine an Mg-rich composition closer to that of forsterite is required. Refractory olivine is used in the steel industry and in the manufacture of precast refractory linings for incinerators, where its heat-storage properties can result in more complete combustion, and its low expansion rate allows heat cycling without spalling of the lining.
5) *Highly refractory cements* (particle size range 0 – 0.2 or 0 – 1 mm). These are formulated as for forsterite bricks, but with a higher content of fluxing materials.
6) *Highly refractory ramming mixtures* with similar compositions to those of bricks. These are incorporated into furnace linings by manual or compressed-air ramming.
7) *Sand-blasting material* which does not involve a silicosis hazard (unlike silica). Olivine is used to some extent as a blasting abrasive and as a grit in water-jet cutting. Together with other minerals, it is used in cleaning buildings and occasionally for etching structural steel.
8) *Olivine bricks as heat reservoirs* in electrical night storage heaters.

2.5. Andalusite

Andalusite [*12183-86-1*] belongs to the nesosubsilicates (orthosilicates that contain isolated $[SiO_4]$ tetrahedra and additional nontetrahedral anions), and, like kyanite (Section 2.6) and sillimanite (Section 2.7), is a mineral of the Al_2SiO_5 group.

Structure and Mineralogy. Al_2SiO_5 can form three different crystal structures, i.e., Al_2SiO_5 exhibits polymorphism in the form of andalusite, sillimanite and kyanite. In all three phases one aluminum atom (Al_I, Fig. 25) always has the coordination number six, i.e., it is surrounded octahedrally by six oxygen ions. The $[Al_IO_6]$ octahedra are linked by common edges to form chains parallel to the *c* axis. The c_0 dimension in all three minerals is therefore approximately the same (ca. 0.55 nm). The other aluminum atom (Al_{II}, Fig. 25) in andalusite has the coordination number five, in sillimanite four, and in kyanite six. The chains of octahedra in andalusite are held together by $[AlO_5]$ and $[SiO_4]$ groups. In andalusite none of the bonds break preferentially, so that andalusite has a higher Mohs hardness (7 1/2) than sillimanite or kyanite. Libethenite $Cu_2[OH/PO_4]$, adamine $Zn_2[OH/AsO_4]$ and eveite $Mn_2[OH/AsO_4]$ are isotypical with andalusite.

The formula of andalusite is $Al^{[6]}Al^{[5]}[O/SiO_4]$. It forms orthorhombic – dipyramidal crystals with space group D_{2h}^{12} – Pnnm; lattice constants: $a_0 = 0.778$ nm, $b_0 = 0.792$ nm; $c_0 = 0.557$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.982 : 1 : 0.703$; $Z = 4$.

Some Mn^{3+} and Fe^{3+} and a small amount of Cr^{3+} and Ti^{4+} always replace the aluminum in andalusite (usually 2 – 3 atom % in total). Viridinite is a variety that contains several percent of Mn_2O_3 and Fe_2O_3 ($a_0 = 0.7808$ nm, $b_0 = 0.5929$ nm, $c_0 = 0.5567$ nm). Manganese andalusite is also known. Andalusite has a greater potential for ionic substitution (diadochy) than kyanite and sillimanite.

Andalusite occurs rather widely as intergrown, fairly large, thick columnar crystals. It can also occur in aggregates that may be granular, in the form of bunches or tufts, as radially arranged columns, and as coarsely tangled masses and lenses. Andalusite also occurs as chiastolite in argillaceous and spotted slates (Knotenschiefer), forming yellowish-white crystals containing a gray to black carbonaceous impurities in a regular manner.

Andalusite usually has a matt, cloudy, translucent, or opaque appearance and can be red, green or reddish-gray with a vitreous luster. It shows a variable degree of cleavage parallel to {110}. Transparent crystals of gem quality are rare (California, Brazil).

Andalusite represents a typical example of a mineral formed by contact metamorphism (hornfels, etc.). Typically, it often occurs in argillaceous rocks with a low lime content in contact aureoles around igneous intrusions. In places, andalusite is found in granite when the magma resorbed aluminum-rich sedimentary rocks. This mineral is also found in pegmatites and in accidental blocks (volcanic ejecta). Furthermore, andalusite is observed in mesozonal, aluminum-rich mica schists along with sillimanite, muscovite, biotite, almandine, and in some places also with cordierite and staurolite, although never with microcline.

Properties. The following physical properties are important for industrial applications:

Density: 3.09 – 3.16 g/cm^3
Mohs hardness: 7 1/2
Phase changes:
> 1350 °C: decomposition to mullite and vitreous SiO_2; on cooling, volume increases by 3 – 6 % with respect to the starting material
1840 °C: incongruent melting point, conversion to corundum and vitreous SiO_2
1920 °C: complete fusion
Specific heat capacity (0 – 100 °C): 0.705 J g^{-1} K^{-1}
Thermal conductivity: at 0 °C 2.26 kJ m^{-1} h^{-1} K^{-1}, at 189 °C 4.08 kJ m^{-1} h^{-1} K^{-1}

The ideal chemical composition is the same as that of kyanite and sillimanite: 62.93 wt % Al_2O_3, 37.07 wt % SiO_2.

Andalusite is not attacked by mineral acids apart from hydrofluoric acid, which attacks it very slowly in the cold, but readily when hot. Andalusite is stable towards dry HCl and Cl_2. Fused KOH strongly attacks andalusite, as does a solution of CO_2 in water at 160 °C and 0.6 – 0.7 MPa.

Deposits and Extraction. Andalusite deposits are mined in France (Côtes du Nord), Portugal (Porto), the Republic of South Africa (in three areas of the Transvaal: Groot Marico, Lydenburg, Thabazimbi), the People's Republic of China and the United States (White Mountains; Hawthorne, Nevada).

The overlying rocks above the andalusite-bearing schists and sands are not usually very

Figure 25. Structure of andalusite, $Al^{[6]}Al^{[5]}[O/SiO_4]$
A) Projection parallel to *c* on (001); B) $[AlO_6]$ octahedra along the *c* axis

thick. Therefore, extraction is mainly by opencast mining using explosives, compressed air hammers and front loaders.

The French deposits contain schists in which the andalusite content, which is coarsely crystalline, is ca. 15 %. The andalusite crystals are up to several centimeters long in the direction of the *c* axis and 1 – 4 mm wide in the direction of the *a* and *b* axes. Accompanying minerals are biotite, iron-rich chlorite, and quartz. The material is processed to give two grades of andalusite concentrate: 59 % Al_2O_3 with 1 % Fe_2O_3, and 53 % Al_2O_3 with 1 % Fe_2O_3. Processed andalusite sand has a particle size of 0.3 – 1.6 mm and is slightly colored.

In the Republic of South Africa, the andalusite is interbedded with schists. The primary deposits consist of andalusite-bearing schists in which the average content of extractable andalusite is 7 – 10 %. The secondary deposits are alluvial andalusite sands (placer deposits), in which the content of extractable andalusite is 10 – 50 %, reaching 50 – 60 % in the Burgersfort mine (Zimro).

In the White Mountains area of the United States 3 – 20 m thick deposits containing 70 – 80 % andalusite occur. In Hawthorne, Nevada, the vein-like deposits are 0.5 – 1.5 m thick and 1000 m long. They are extracted to a depth of 30 m.

Recently, a promising deposit was found near Tomduff in the Republic of Ireland. It consists of a series of andalusite schists and quartz-biotite schists, is 200 m thick, and continues for 3000 m along the strike.

Ore Treatment and Commercial Products. The broken schists and sands are crushed to a grain size of 0.3 – 1.6 mm (or to 0.6 – 3.35 mm by Weedons Minerals). Biotite, chlorite and other ferromagnetic minerals are removed by high-intensity magnetic separators. Quartz and other low-density minerals are removed by a wet process using settling tanks. These processes are described in detail elsewhere (→ Magnetic Separation; → Gravity Concentration). The dried andalusite concentrate is the commercial product. Commercial grades, with the amounts of major impurities, are listed in Table 10.

The refractory properties of the mullite – vitreous SiO_2 matrix (that is formed from the andalusite concentrate by reaction at high temperature) improve with increasing Al_2O_3 content (ideally 62.93 %). They also improve with decreasing TiO_2 content (max. 2 %), decreasing Fe_2O_3 content (< 1 % if possible) and decreasing alkali-metal content (fluxing effect).

Uses. Andalusite, like sillimanite, kyanite and synthetic mullite, is an important raw material for the production of highly refractory materials and is marketed with sillimanite and kyanite as "sillimanite minerals". The increase in volume when andalusite is fired above 1350 °C is small (3 – 6 %), whereas the corresponding increase for kyanite is considerably greater.

Andalusite of the proper fineness is suitable for use as a filler in coatings and plastics subjected to great mechanical or chemical stress, due to its crystal chemical properties and mor-

Table 10. Grades of andalusite concentrates

Company ∗	Grade	Al_2O_3, wt %	Fe_2O_3, wt %
Denain Anzin	keraphalite	59	≃ 1.531

Lager Mining		57	1.2 – 2
Hoogenoog Andalusite		59.9 – 60	< 1

∗ Denain Anzin Mineraux is located in Paris, all other companies are in the Republic of South Africa.

phology. The length : width ratio of the crystals is 10 : 1 – 50 : 1. However, the energy required for grinding is considerable owing to the hardness of the mineral.

Economic Aspects. The annual consumption of crude rock by the Federal Republic of Germany, including material fired to > 1350 °C, is ca. 51 000 t. In France the annual consumption of "sillimanite minerals" is ca. 30 000 t and in the Republic of South Africa ca. 135 000 t. The Western countries have a consumption of ca. 170 000 t and the worldwide consumption of "sillimanite minerals" is ca. 300 000 – 350 000 t/a in the last few years.

2.6. Kyanite

Kyanite [*1302-76-7*] (cyanite, disthene) belongs to the nesosubsilicates (orthosilicates that contain isolated $[SiO_4]$ tetrahedra and additional nontetrahedral anions) and, like andalusite (Section 2.5) and sillimanite (Section 2.7), is a mineral of the Al_2SiO_5 group.

Structure and Mineralogy. One aluminum atom (Al_I, Fig. 26) always has the coordination number six, the $[Al_IO_6]$ octahedra being linked by common edges to form chains parallel to the *c* axis. The other aluminum atom (Al_{II}, Fig. 26) in kyanite also has the coordination number six. The chains of $[Al_IO_6]$ octahedra are joined to other $[Al_{II}O_6]$ octahedra, which are attached alternately to the right and left and are also linked via isolated $[SiO_4]$ tetrahedra to form stable planar structures parallel to [100]. Vacant octahedra form open channels parallel to (001). This accounts for the extension of the crystals in the *c* direction [001], giving them a ruler-like appearance and, on the other hand, complete cleavage along (100) and the anisotropic hardness, i.e., 4 – 4 1/2 Mohs in the *c* [001] direction, and 6 – 7 Mohs perpendicular to this in the *b* [010] direction.

Figure 26. Structure of kyanite, $Al^{[6]}Al^{[6]}[O/SiO_4]$, projection parallel to *c* on (001)
Due to the low degree of symmetry, there are four different types of aluminum atoms, all with six- coordination. Al_I and Al_{II} in kyanite correspond to Al_I in sillimanite (see Fig. 27) and andalusite (see Fig. 25) and form chains of octahedra.

The mineralogical formula of kyanite is $Al^{[6]}Al^{[6]}[O/SiO_4]$. It forms triclinic – pinacoidal crystals with space group $C_i^1 - P\bar{1}$; lattice constants: $a_0 = 0.710$ nm, $b_0 = 0.774$ nm, $c_0 = 0.557$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.917 : 1 : 0.720$; $\alpha = 90°05^1/^2{}'$, $\beta = 101°02'$, $\gamma = 105°44^1/^2{}'$; $Z = 4$. The oxygen ions in kyanite are approximately in cubic close packing, yielding the highest density (3.53 – 3.65) of the Al_2SiO_5 polymorphs.

Ionic substitution is possible to a somewhat larger extent with kyanite than with sillimanite (Section 2.7), but is appreciably less than with andalusite (Section 2.5). Fe^{3+} can replace alu-

minum in the lattice to a small extent, as can Cr^{3+} in rare cases, which leads to an increase in the refractive indices. Low levels of alkali metals and hydroxide have also been found in completely transparent kyanite crystals.

Kyanite occurs mainly as radially arranged lamellar aggregates that may be tangled together. The crystals are intergrown, shaped like broad stalks or rulers that extend in the direction of the *c* (001) axis, and are frequently bent into a slightly waved shape and transversely striated due to translational movement. Kyanite is translucent to transparent and is usually blue, but is often flecked and irregularly colored. It can also be white or yellowish-white (rhatizite), pink or pinkish, with a nacreous or vitreous luster. Cleavage parallel to {100} is fully developed, is well-marked parallel to {010} and is poor or fibrous parallel to {001}. Cleavage parallel to {001} has the character of a fibrous fracture, since {100} also represents a slip plane with [001] as the slip direction.

Kyanite is a typical mineral of (aluminum-rich) metamorphic rocks, especially of mesozonal crystalline rocks, in which it is mainly associated with rutile, staurolite, almandine, hornblende, micas and corundum. It is occasionally found in gneisses, micaceous schists, granulites and eclogites. In catazonal rocks, kyanite only occurs in high-pressure formations because sillimanite is stable at lower pressures. Kyanite is the high-pressure form of Al_2SiO_5; andalusite and sillimanite both crystallize at lower pressures, with sillimanite being the high-temperature form.

On heating at atmospheric pressure, both kyanite and andalusite are converted monotropically to sillimanite. The conversion of kyanite to mullite and vitreous SiO_2 is of industrial importance, because these reactions take place above ca. 1200 °C.

Properties. The following physical properties of kyanite are important for industrial applications:

Density: 3.53 – 3.65 g/cm^3
Mohs hardness: $4\frac{1}{2} - 7$
Phase changes:
< 1300 °C: unstable with respect to sillimanite 1335 °C: decomposition to mullite and vitreous SiO_2, on cooling, volume increases by 14 – 16 % with respect to the original mineral
1830 °C: incongruent melting, forming corundum and vitreous SiO_2
1920 °C: complete fusion

The ideal chemical composition is 62.93 wt % Al_2O_3, 37.07 wt % SiO_2.

Kyanite is stable towards strong mineral acids. Attack by chlorine and dry HCl is only slight at red heat. Hydrofluoric acid decomposes ca. 84 % of the material. Molten KOH strongly attacks kyanite. However, there is little attack by aqueous solutions of alkali hydroxides.

Deposits and Extraction. Kyanite is a common constituent of crystalline schists. Few deposits can be extracted economically, and these consist mainly of schists that contain kyanite in crystal aggregates or as small coarse masses. Kyanite can also occur in lenses in pegmatites and in similar formations or nest-like masses in quartz veins.

The world's largest reserves are in the United States and stretch from northeast Georgia to South and North Carolina and Virginia in the Appalachians. Other large deposits are found in Canada and the Republic of South Africa. Deposits in the United States, Brazil, the Republic of South Africa, Zimbabwe, Spain and India are exploited commercially.

In the United States, kyanite-containing quartzite is extracted using explosives and excavation, followed by grinding and flotation. The flotation concentrate contains 91 % kyanite and 2 – 5 % iron oxides, with silica making up the balance. The Fe_2O_3 content of the dried concentrate is reduced to 0.16 – 0.94 % by high-intensity magnetic separation. The commercial product contains 59.5 – 61.8 % Al_2O_3.

A kyanite – sillimanite concentrate is produced as a byproduct of the treatment of zirconium sands in Australia.

In Spain, alluvial deposits of kyanite-containing gravel are dug by front-loading equipment. After washing and wet tumbling, the kyanite is picked out by hand, calcined at 1480 °C, crushed and classified into grain sizes of 0 – 1, 1 – 3 and 3 – 5 mm. Its composition is Al_2O_3 58 – 63 %, Fe_2O_3 0.5 – 1.5 %, TiO_2 0.15 – 0.5 % and alkali metals ca. 0.7 %.

Uses. Kyanite is an important raw material for refractory products (ceramics) and is marketed with sillimanite and andalusite as an industrial mineral.

Unlike sillimanite, andalusite and mullite, kyanite undergoes a large volume increase (16–18 %) when heated above 1325 °C. Powdered kyanite is therefore used in mixtures for ceramic and refractory products to compensate for shrinkage on firing. The refractory properties of the matrix of mullite and vitreous SiO_2 formed from kyanite concentrates at high temperature are a function of its chemical composition.

2.7. Sillimanite

Sillimanite (fibrolite) belongs to the nesosubsilicates (orthosilicates that contain isolated $[SiO_4]$ tetrahedra and additional nontetrahedral anions) and, like andalusite (Section 2.5), kyanite (Section 2.6) and mullite, is a mineral of the Al_2SiO_5 group.

Structure and Mineralogy. One aluminum atom (Al_I, Fig. 27) always has the coordination number six. The $[Al_IO_6]$ octahedra are linked by common edges to form chains parallel to the *c* axis. The other aluminum atom (Al_{II}, Fig. 27) in sillimanite has the coordination number four. The chains of octahedra in sillimanite are laterally bonded by $[Al_{II}O_4]$ and isolated $[SiO_4]$ tetrahedra which form bands of $[Al_2Si_2O_{10}]$ tetrahedra from two linked chains of $[AlSiO_6]$ (see Fig. 27). The four- coordinated aluminum in sillimanite cannot be substituted by silicon. Parallel to *b* (010), very strongly bonded layers are formed from the $[AlO_6]$ chains and $[Al_2Si_2O_{10}]$ bands. These can easily be cleaved from the neighboring layers by separation at the apices of the $[AlO_6]$ octahedra. This explains the perfect cleavage of sillimanite parallel to $\{010\}$. The chain structure also accounts for the generally fibrous structure of sillimanite crystals (fibrolite). As sillimanite has chains of tetrahedra, it is classified as an inosilicate (chain silicates, i.e., silicates with infinite chains of $[SiO_4]^{4-}$ tetrahedra).

The mineralogical formula of sillimanite is $Al^{[6]}Al^{[4]}[O/SiO_4]$. It forms orthorhombic–dipyramidal crystals with space group D_{2h}^{16}–Pbnm; lattice constants: $a_0 = 0.744$ nm, $b_0 = 0.760$ nm, $c_0 = 5.75$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.979 : 1 : 0.757$; $Z = 4$.

Figure 27. Structure of sillimanite, $Al^{[6]}Al^{[4]}[O/SiO_4]$, projection parallel to *c* on (001)

Sillimanite has low tolerance to ionic substitution, the aluminum atoms in the lattice being replaceable only by some Fe^{3+} and a small amount of titanium. Although alkali metals and hydroxide are often reported, they either occupy the spaces in the lattice or are impurities in the mineral.

Sillimanite usually forms columnar, fibrous or matted aggregates. Single crystals are rare, but large crystals (about the size of a fist) are produced synthetically. Dense masses intergrown with quartz are known as fibrous quartz. Sillimanite is yellowish gray, gray, brownish or grayish-green in color, is transparent to translucent and has a vitreous luster or a silky luster when in fibrous form.

Sillimanite is usually a common minor constituent of ortho- and paragneisses (e.g., feldspar–quartz–cordierite gneisses), micaceous schists, granulites, eclogites, and of pegmatites and quartz veins that occur in these rocks. It also occurs in contact-metamorphic rocks, sometimes in the form of very fine fibers. At high temperature (> 650 °C theoretical, ca. 1480 °C in practice), kyanite and andalusite are converted to sillimanite. At even higher temperature (1545 °C), sillimanite is converted to mullite, which has a lower SiO_2 content, and vitreous SiO_2. Accompanying minerals include feldspars, quartz, cordierite, muscovite, biotite, almandine, staurolite, corundum, andalusite, kyanite, rutile and ore minerals such as magnetite and ilmenite.

Properties. Sillimanite is the modification of $Al_2[O/SiO_4]$ that is stable at high temperature and low pressure. Cleavage on (010) is fully developed, but the fracture is uneven.

The following physical properties are important for industrial applications:

Density: 3.23 – 3.25 g/cm^3 (2.95 g/cm^3 after heating at 1545 °C)
Mohs hardness: 6 – 7
Phase changes:
1545 °C: decomposition to mullite and a vitreous matrix containing ca. 95 % SiO_2
1810 °C: liquid phase reaction to form corundum and a vitreous phase
1860 °C: complete fusion
> 1860 °C: boiling of the melt, producing a vapor phase with a high SiO_2 content and a liquid phase with a high Al_2O_3 content
Temperature stability limit in an oxidizing atmosphere: 1600 °C
Softening temperature under a load of 2 kg/cm^2: 1550 – 1650 °C
Thermal coefficient of expansion: at 20 – 100 °C 2.8×10^{-6} K^{-1}, at 300 °C 4.1×10^{-6} K^{-1}, at 800 °C 4.3×10^{-6} K^{-1}, and at 1200 °C 4.6×10^{-6} K^{-1}.
Specific heat capacity: at 300 °C 0.92 kJ kg^{-1} K^{-1}, at 1200 °C 1.0 kJ kg^{-1} K^{-1}
Thermal conductivity: at 300 °C 5.4 – 5.9 kJ m^{-1} h^{-1} K^{-1}, at 1200 °C 4.6 – 5.0 kJ m^{-1} h^{-1} K^{-1}

Sillimanite ($Al_2O_3 \cdot SiO_2$) has the ideal chemical composition 62.93 wt % Al_2O_3, 37.07 wt % SiO_2. It is insoluble in water, is decomposed by ammonium fluoride on heating and is resistant to weathering.

Like the other $Al_2[O/SiO_4]$ modifications, sillimanite is very difficult to melt and highly resistant to acids. Its chemical resistance when used as a refractory material is as follows:

Toward reducing atmospheres	moderate
Toward carbon	moderate
Toward acidic fluxes	good
Toward basic fluxes	moderate
Toward molten metals	good

Deposits and Extraction. Sillimanite deposits occur in Australia, India, Namibia, the Republic of South Africa, Brazil and Sri Lanka. The sillimanite is usually associated with quartz and kaolin (Australia) or with corundum (India, Republic of South Africa). World production is ca. 30 000 t/a.

The deposits are mainly extracted by opencast mining. Due to the hardness of the rock, drilling and blasting are necessary. The rock is crushed and classified with screening equipment.

Quality Specifications (see Table 11). Sillimanite used in the production of clay- containing refractory products of group 1 (→ Refractory Ceramics and ISO R 1109) must contain at least 56 % Al_2O_3 (ISO R 1109).

Uses. The most important use for sillimanite is in refractory materials. It is normally precalcined to ca. 1550 °C to convert the sillimanite to sinter-mullite (see Section 2.8), which has a high thermal shock resistance and a very low coefficient of thermal expansion (5.6×10^{-6} K^{-1} at 20 – 1000 °C). Sillimanite with a high corundum content is more resistant to slags with a high iron oxide content. Mechanically cut natural rock and bonded bricks are only used for lining blast furnaces, glass melting furnaces and roasting furnaces.

Coarsely ground material is used for highly refractory mortars and ramming compounds. Finely ground material is used in the production of architecturally applied ceramics (e.g., sanitary ware or wall and floor tiles).

Sillimanite is used as a filler in paints, coatings, adhesives and plastics, especially in systems cross-linked by polyaddition due to the nature of its surface (functional SiOH groups for polyaddition and polycondensation), high hardness, and ability to reinforce the matrix due to its acicular (i.e., needle-like) or fibrous structure.

2.8. Mullite

Mullite [*1302-93-8*] belongs to the nesosubsilicates (orthosilicates that contain isolated $[SiO_4]$ tetrahedra and additional nontetrahedral anions) and is very similar to sillimanite (Section 2.7) in its structure and properties.

Structure and Mineralogy. Mullite has a sillimanite structure, but differs from sillimanite in having a deficiency of oxygen. Since some of

Table 11. Sillimanite specifications (wt %)

	Al_2O_3	SiO_2	Fe_2O_3	TiO_2	Na_2O/K_2O
Highly enriched	59 – 65	39 – 33	< 1	max. 2	max. 0.1
With a high corundum content	65 – 78	33 – 20	< 1	max. 2	max. 0.1

the silicon atoms in the $[SiO_4]$ tetrahedra are replaced by Al^{3+}, some of the positions normally occupied by oxygen atoms are left unoccupied to maintain charge balance. Therefore, mullite has a higher aluminum content than sillimanite and has a chemical composition between $3\,Al_2O_3 \cdot 2\,SiO_2$ and $2\,Al_2O_3 \cdot SiO_2$.

The mineralogical formula of mullite is $Al_4^{[6]}Al_4^{[4]}\,[O_3(O_{0.5}, OH, F)/Si_3AlO_{16}]$ or $Al_4^{[6]}Al_4^{[4]}\,[O_{4-x/2}/Si_{4-x}Al_xO_{16}]$, where $x = 1.0 - 1.6$. It forms orthorhombic – dipyramidal crystals, with space group D_{2h}^9 – Pbam; lattice constants: $a_0 = 0.7566$ nm, $b_0 = 0.7682$ nm, $c_0 = 0.2884$ nm (i.e., half of c_0 for sillimanite); the axial ratio is $a_0 : b_0 : c_0 = 0.985 : 1 : 0.375$; $Z = 1$. Synthetic mullite, $3\,Al_2O_3 \cdot 2\,SiO_2$, has lattice constants $a_0 = 0.7576$ nm, $b_0 = 0.7688$ nm, $c_0 = 0.2884$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.981 : 1 : 0.375$. Synthetic mullite, with the composition $2\,Al_2O_3 \cdot SiO_2$, has lattice constants $a_0 = 0.7576$ nm, $b_0 = 0.7687$ nm, $c_0 = 0.2883$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.986 : 1 : 0.375$.

Another modification of Al_2SiO_5 appears to be a newly discovered phase in the system $Al_2O_3 - SiO_2 - H_2O$, crystallizing in the orthorhombic – dipyramidal system, with space group D_{2h}^9 – Pbam; lattice constants: $a_0 = 0.755$ nm, $b_0 = 0.827$ nm, $c_0 = 0.283$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.913 : 1 : 0.342$.

These cells of mullite are subcells (i.e., the ordering effects of the oxygen defects and of the silicon and aluminum ions are neglected). There are always six (silicon + aluminum) ions per subcell in mullite and twelve (silicon + aluminum) ions with doubled c lattice constants in sillimanite. In a few cases, ordering is found, and additional superlattice reflexes are observed corresponding to a larger unit cell, e.g., $a_0 = 3 \times a_0'$, $b_0 = 8 \times b_0'$, and $c_0 = 6 \times c_0'$, and $a_0' = 0.74$ nm, $b_0' = 0.76$ nm and $c_0' = 0.29$ nm. Sillimanite is ordered, with $c_0 = 2 \times c_0'$, and the same must also be true for "prägite", $2\,Al_2O_3 \cdot SiO_2$, which is only known as a synthetic product.

In naturally-occurring mullite, Fe^{3+} or Ti^{4+} can replace Al^{3+} to a small extent (up to 1 wt % Fe_2O_3 and up to 2 wt % TiO_2).

Natural mullite forms small pseudotetragonal colorless, white, yellowish or reddish crystals with columnar or needle-like development in the c [001] direction. Cleavage is well developed on (010), but is difficult to observe due to the normally small size of the crystals. Synthetic mullite is colorless, but green when Al^{3+} is substituted by Cr^{3+}. In synthetic products (e.g., chamottes and porcelain bodies), mullite has extremely fine crystals (< 1 µm). When these crystals come into contact with slags, larger prismatic crystals often form at the reaction interface. Melt-mullite products contain even larger crystals.

Occurrence and Formation. Mullite is not very often found in natural rocks. It greatly resembles sillimanite, with which it can easily be confused. It occurs almost entirely in contact-metamorphosed formations in primary argillaceous sandstones and phyllites contained as inclusions in basalts and also in a narrow exogenous contact zone (buchite) with anatexis at the edge of basalt pipes. The name mullite stems from its occurrence in sintered lumps of sedimented clay in the basalt of the island of Mull in Scotland.

The formation of mullite in synthetic products, such as chamotte products, porcelain and high-aluminum slags (e.g., from coal and coke) is of great industrial importance. It is formed when kaolinite is strongly heated or calcined to 1200 – 1600 °C and is also produced when kyanite, andalusite, sillimanite or other aluminosilicates are strongly heated, decomposing them into mullite and vitreous SiO_2. At 1810 °C, mullite dissociates into an equilibrium mixture of corundum and molten SiO_2. However, some investigations have shown that mullite can have a congruent melting point. In silicate slags, mullite only crystallizes if minor amounts of basic oxide components are present. Very small amounts of Na_2O, etc., significantly reduce the dissociation temperature of mullite.

Properties. The following physical properties are important for industrial applications:

Density: 3.10 – 3.16 g/cm^3
Mohs hardness: 6 – 7
Phase changes:
1810 °C: incongruent melting with decomposition to corundum and a vitreous phase
1920 °C: complete melting
Crystallization:
Occurs readily from the melt, well-developed crystals (usually finely matted together) are formed, even on very rapid cooling
Temperature stability limit in an oxidizing atmosphere: 1850 °C
Thermal expansion coefficient:
at 500 °C 4.0×10^{-6} K^{-1},
at 1000 °C 4.5×10^{-6} K^{-1},
at 1500 °C 5.3×10^{-6} K^{-1}
Specific heat capacity:
at 25 °C: 0.633 Jg^{-1} K^{-1}
Thermal conductivity:
at 100 °C 22.2 kJ m^{-1} h^{-1} K^{-1}
at 500 °C 15.5 kJ m^{-1} h^{-1} K^{-1}
at 1000 °C 14.2 kJ m^{-1} h^{-1} K^{-1}
Electrical resistivity:
at 500 °C 3×10^{-5} Ω · cm,
at 1000 °C 7×10^{-3} Ω · cm,
at 1500 °C 5×10^{-2} Ω · cm

The ideal composition of mullite is 71.8 wt % Al_2O_3, 28.2 wt % SiO_2. Both natural and synthetic mullite often deviate from the composition 3 Al_2O_3 · 2 SiO_2 (60 mol % Al_2O_3), and an Al_2O_3 content of 63 mol % is not uncommon. Mullite is obtained as a solid crystalline mass by sintering a mixture of Al_2O_3 and SiO_2 in the molar ratio 3 : 2 at 1775 °C.

Water and strong mineral acids do not attack mullite even when heated. Mullite also resists concentrated hydrofluoric acid at room temperature for long periods, although rapid decomposition takes place on heating to 70 – 100 °C. Resistance to molten metals and basic compounds is moderate. To achieve complete breakdown, mullite must be fused with sodium peroxide or a mixture of sodium carbonate and borax glass.

The chemical resistance of mullite in refractory materials is:

Toward reducing atmospheres	moderate
Toward carbon	moderate
Toward acidic fluxes	good
Toward basic fluxes	moderate
Toward molten metals	moderate

Deposits. Natural mullite is mined from only one significant deposit in northern Transvaal in the Republic of South Africa (Otavi Mining Company). The production rate is ca. 5000 t/a.

Synthesis. Synthetic mullite is of considerable economic importance. Outputs are as follows: United States ca. 27 000 t/a , United Kingdom: > 12 000 t/a. Producers in *Germany* Vereinigte Aluminiumwerke and Hülst AG; in the *United Kingdom* Keith Ceramic Materials Ltd.; in *Hungary* Hungary "Motim" Alumina and Electrocorundum Factory; in the *United States* Washington Mills Electro Minerals Corp.; in *Brazil* Elfus Ltda.; in *Japan* Showa Denko KK. For the very great demands placed on refractory materials, mullite is superior to the sillimanite minerals (sillimanite, andalusite, kyanite), which can be converted into crystalline mullite and a vitreous SiO_2 matrix only after calcination.

Two main grades of synthetic mullite are produced: fused mullite (electromullite) and sinter mullite. Fused zirconia mullite is also produced. In general, sintered mullite is manufactured in a rotary kiln, whereas fused mullite is produced either in a Higgins furnace or using a tilt-pour electric arc furnace.

Electromullite. A mixture of kaolinite and calcined aluminum oxide in a precisely controlled ratio is melted in an electric arc furnace. The product is crushed and classified into various grain sizes. In the selection of the raw materials, careful attention must be paid to levels of impurities, especially iron, other heavy metal ions and alkali metals. Metallic contaminants generated by abrasion of the crushing and classifying equipment are removed by magnetic separators.

The reaction product contains up to 95 % mullite and 76.4 – 75.2 % Al_2O_3. The following composition is given for an English grade: mullite 95 %, vitreous matrix and corundum 5 %, SiO_2 23 %, Al_2O_3 76.2 %, Fe_2O_3 0.1 %, CaO 0.2 %, MgO 0.1 %, $K_2O + Na_2O$ 0.4 %. The melting point (Seger cones) is ca. 1900 °C, and the material withstands long-term loading at 1750 °C.

Sinter mullite. The purity of this material is somewhat lower than that of electromullite. Briquettes of kaolinite, aluminum hydroxide and some water for bonding are sintered in tunnel furnaces at $\leq 1750\,°C$ and are then crushed and classified into size fractions. The product contains ca. 86 % mullite (i.e., 72.9 % Al_2O_3), ca. 0.7 % Fe_2O_3 and small amounts of other impurities. It withstands long-term loading at 1700 °C.

The sinter mullite produced by the Vereinigte Aluminiumwerke (Germany) has the following specification: Al_2O_3 72 %, SiO_2 16 %, density 3.1 g/cm^3, mean particle diameter 30 µm, maximum particle size 100 µm, color white.

Uses. The main area of use for mullite is in highly refractory materials for lining metallurgical melting furnaces and glass melting tanks, along with other applications where strongly acidic attack takes place at high temperatures. Mullite is also used as a raw material for porcelain for electrical insulation, as an opacifier for high-quality enamels, as a polishing medium (due to its great hardness), as a filler in plastics and paints, and as an abrasion-resistant reinforcing filler in coatings for surfaces and roadways that are subject to severe mechanical stress.

Some of the synthetic mullite's distinguishing attributes (e.g., excellent thermal shock resistance, good hot strength under load, volume stability at high temperatures, low shrinkage, high resistance to aggressive melts and slags, good abrasion resistance, and additionally high creep resistance of fused mullite) also permit its wide use. Refractories for the steel and glass industries are the most important market for sintered and fused mullite and fused zirconia mullite. Synthetic mullite is also used in the ceramic industry.

2.9. Vermiculite

Structure and Mineralogy. Vermiculite belongs to the phyllosilicates (sheet or layer silicates) and has a mica-like foliated structure. It displays the typical properties of the montmorillonite – saponite group to a pronounced degree: the layers have a greater excess charge and a greater capacity for cation exchange than talc or pyrophyllite layers. The structure contains layers similar to those found in talc, pyrophyllite (→ Talc), biotite, and muscovite (→ Mica, Chap. 2.). It comprises infinite, two-dimensional double silicate layers ${}^{2}_{\infty}[Si_4O_{10}]^{4-}$ (Fig. 28). Part of the Si^{4+} is substituted by Al^{3+}, and the terminal oxygen ions of the $[(Si, Al)O_4]$ tetrahedra are always on the same side (Fig. 28 A). The hexagons formed by these oxygen ions have hydroxyl groups at their centers. In this double layer, the oxygen layers formed from O (bound to one Si) and OH groups face each other directly, forming octahedral voids. These voids are occupied mainly by Mg^{2+}, but also by Fe^{3+} and Al^{3+} (Fig. 28 B), which hold together the two Si_2O_5/OH sheets. The octahedral voids are formed by four oxygen atoms and two hydroxyl groups. Due to the partial replacement of Si^{4+} by Al^{3+}, the double layer pocket $Mg_3[(SiAl)_4O_{10}/(OH)_2]$ has a slight excess negative charge, which is compensated by additional cations, e.g., Mg. These cations, together with water molecules, are interlayered between the layer pockets, usually Mg^{2+} or, less frequently, Ca^{2+}. This interlayer (intermediate layer) has a positive excess charge and consists of a double layer of $H_2O - Mg^{2+} - H_2O$, in which the H_2O locations may be only partially occupied. Each H_2O in this interlayer is linked to an oxygen atom in the neighboring silicate double layer by a hydrogen bond. Thus, vermiculite structurally resembles a kind of talc expanded by H_2O that has been formed from (hydrous) mica by potassium depletion.

The swelling capacity (ability to be hydrated) of vermiculite is due to the fact that the silicate layers have a slight excess negative charge and thus repel each other; this facilitates the penetration of water into the interlayer with its small positive excess charge. Unbonded water can be removed from the vermiculite by heating to $< 110\,°C$, but the water fixed by cations in the interlayer is only released at $> 300\,°C$. On heating, the water in the interlayer is released either gradually or, on sudden heating, with expansion and formation of worm-shaped structures. Exfoliation causes unidirectional expansion perpendicular to the cleavage plane (001) and the volume increases greatly (from 8- to 50-fold). If the trapped water is driven off slowly, even at 250 °C vermiculite shows no exfoliation. Exfoliation of vermiculite can also be caused by treatment with hydrogen peroxide, which leads

Figure 28. Structure of vermicullite
A) The two-dimensional infinite silicate layer $[(Si, Al)_4O_{10}]^{x-}$, projection parallel to *c* on (001); B) Intermediate $H_2O-Mg^{2+}-H_2O$ layer between two silicate double layers, projection perpendicular to the *a* axis

to release of oxygen by reaction with interlayer magnesium ions.

The mineralogical formula of vermiculite is:

$$(Mg, Fe^{3+}, Al)_3[(OH)_2/Al_{1.25}Si_{2.75}O_{10}] \cdot Mg_{0.33}(H_2O)_4$$

or

$$Mg_{2.36}Fe^{3+}_{0.48}Al_{0.16}[(OH)_2/Al_{1.28}Si_{2.72}O_{10}]^{0.64-} \cdot Mg_{0.32}(H_2O)_4$$

Vermiculite forms monoclinic crystals, with the following lattice constants: $a_0 = 0.533$ nm, $b_0 = 0.918$ nm, $c_0 = 2 \times 1.436$ nm; $\beta = 97°$; the distance between the layers, $d_{002} = 1/2c \cdot \sin\beta$, is ca. 1.425 nm.

Batavite and *protovermiculite* are related to vermiculite and have similar compositions and lattice constants. In nickel – vermiculite, a high proportion (10 – 25 atom %) of the Mg^{2+} ions is substituted by Ni^{2+}. The alkali metal content of vermiculite is always very small, and high contents are due to replacement of layers of vermiculite by layers of biotite. An increase in the number of these biotite layers can eventually lead to the formation of *hydrobiotite.* Another "mixed-layer" mineral is formed by interlayering of the vermiculite with chlorite; when there is a high iron content, this is known as *jefferisite*, and when the interlayering is regular, with a 1 : 1 ratio, it is known as *corrensite*.

Crystals of vermiculite can reach a size of several centimeters and are then easily confused with biotite. However, they are usually much smaller (2 µm) and can be of the size of clay particles when they occur in sediments. Vermiculite forms monoclinic – pseudohexagonal, short, columnar platelets and mainly occurs in aggregates, which can be bent into worm-like shapes. Fibrous formations can also occur, but are very rare. Vermiculite is brown, bronze-colored, yellow, green, or colorless. Cleavage on (001) is perfect and mica-like, but the platelets are not elastic as in micas.

Deposits of vermiculite often occur in ultrabasic and basic rocks (e.g., pyroxenites, hornblendites, peridotites and their metamorphic equivalents) that have undergone hydrothermal potassium metasomatism and alteration to actinolite – biotite formations. These in turn can be altered in the final stages potassium of this metasomatism or by anhydrous processes to formations of vermiculite and hydrobiotite with relicts of phlogopite, biotite, tremolite and actinolite. The alteration of biotite to vermiculite takes

place by leaching of K^+ from between the silicate layers by hydrothermal activity, percolating ground water or supergene weathering. Vermiculite found as an alteration product of biotite in other metamorphic rocks, such as schists and gneisses, is of similar origin. Vermiculite is only rarely found as an alteration product of mica in marine sediments. In places, vermiculite is found in these sediments as an alteration product of, e.g., chlorite and amphibole. Vermiculite occurs occasionally in marble and in carbonatites. Of some economic importance are vermiculite deposits in the contact zones between ultrabasic and basic rocks and acid intrusives.

Vermiculite is transformed into enstatite and talc on heating to 650 °C. Under increasingly severe hydrothermal conditions ($<$ 200 °C, 70 MPa) it is converted into pseudochlorite, which is itself converted to chlorite and montmorillonite at ca. 550 °C. Vermiculite is easily altered into biotite by potassium metasomatism, although this process is only rarely observed in nature.

Properties. The following physical properties are of interest for industrial applications:

Density: 2.3 – 2.75 g/cm
Mohs hardness: 1 1/2 – 2
Sintering temperature: ca. 1260 °C
Fusion point: 2000 – 2400 °C
mp: 1315 °C
Specific heat capacity: 0.84 kJ kg^{-1} K^{-1}
Thermal conductivity:
0.062 – 0.065 W m^{-1} h^{-1} K^{-1}

Deposits and Extraction. Deposits of economic importance are found in northern Transvaal (Republic of South Africa), at Libby in Montana, at Louise in Virginia, and at Encoree in Laurens County in South Carolina (USA). Further deposits occur in Brazil, Zimbabwe, Kenya, Australia, India, China, Russia and Japan. The vermiculite in these deposits has been formed from phlogopite and biotite by weathering (leaching of K) and hydrothermal alteration. The vermiculite at Encoree in South Carolina occurs in metamorphic rocks in contact with acidic intrusions interspersed with pegmatites. Accompanying minerals include corundum, apatite, serpentine, chlorite, talc and mica.

At Palabora in the Transvaal (Republic of South Africa), the Archean contains a Proterozoic intrusive alkali rock complex that consists of, e.g., pyroxenite, syenite, ultrabasic pegmatoids and carbonatite. This intrusive complex is not only well known for its large copper deposit, but also has an outstanding vermiculite deposit. The vermiculite is an alteration product of phlogopite and is free of asbestos.

The vermiculite bearing zones are selectively extracted by open-cast mining, The ore is loosened by blasting and removed by front loaders. The vermiculite ore is beneficiated by screening, jigging and classification.

Processing has three aims:

1) To separate the vermiculite from the accompanying rock, including rudimentary biotite and phlogopite
2) To delaminate the "books" formed from the vermiculite layers and to split the "leaves" (thickness $>$ ca. 0.8 mm) into "flakes"
3) To classify the flakes into commercial particle size fractions

In the first stage, the rock is usually broken into $<$ 20 mm or $<$ 16 mm granules, and the adhering fine material is removed by washing and screening. Further size reduction separates the vermiculite from the accompanying rock.

In a process operated by Palabora Mining (RSA), the vermiculite flakes are separated from the accompanying rock, including mica, by multistage screening in a horizontal stream of air using various suspension techniques.

The products from both the United States and South Africa are separated into five or six size grades in the millimeter range. The chemical compositions are listed in Table 12. Compared with the North American material, South African vermiculite has undergone a higher degree of physical transformation, gives a higher yield on thermal expansion, and therefore has a higher market value. The difference can also be seen from the chemical composition.

Expansion. Vermiculite, similar to perlite (exhibiting three-dimensinal expansion), expands when heated., but only in one direction (one-dimensional) showing the unique phenomenon of exfoliation by sudden heating to ca. 300 °C or higher. Responsible for this exfoliation is a double layer of water (i.e., an

Table 12. Chemical composition of raw vermiculite (average values, wt %)

Component	Libby, Montana	Encoree, South Carolina	Palabora (RSA)

Total	100.58	100.34	99.88

H_2O-Mg^{2+} – interlayer) trapped between the silicate double layers and liberated upon heating, whereby the rapidly generated vapor cannot be set free without buckling and separating the structural layers. The low thermal conductivity and low density of expanded vermiculite lead to its widespread use in thermal and acoustic insulation applications, as well as in refrigeration engineering. Expansion occurs prerpendicular to the cleavage plane (001).

The suitability of a particular vermiculite for conversion to expanded aggregates can be assessed by differential thermal analysis. However, the temperature – time profile of the furnace used for expansion can only be established with certainty by a laboratory-scale expansion test.

For the expansion and exfoliation of vermiculite various furnaces (e.g., rotary, cascade, vibrating tray, injection tray) can be used. The vermiculite concentrate is heated to between 430 and 1100 °C. The water in the vermiculite is liberated in three stages in 0.25 – 8 s, beginning with a reversible reaction at ca. 150 °C, followed by the onset of exfoliation above 500 °C and vaporization of the residual water at 870 °C. The bulk density is reduced from about 640 – 1040 to 64 – 176 kg/m^3. In some industrial processes, the vermiculite flakes are expanded in 5 – 8 s at 1250 – 1500 °C and then cooled immediately to 400 °C. Since exfoliated vermiculite shows a huge increase in bulk, only shipping of the vermiculite ore or concentrate is economic. Plants for expansion of the vermiculite are therefore generally located close to the consumers.

Uses. In its most important applications, vermiculite is used in its expanded state to exploit its low density, good thermal and acoustic insulating properties and high absorption capacity for liquids.

Vermiculite is utilized in the construction industry for thermal and acoustic insulation. Thermal insulation is the largest market.

Loose filling is widely used in the construction industry and in industrial applications for insulating hollow spaces (e.g., cavity walls), ceilings, walls and roofs. Loose-fill vermiculite is commonly a coarse grade with a particle size up to 16 mm and a bulk density of 56 – 72 kg/m^3. At cryogenic temperatures perlite is a better insulator, but vermiculite is also used in limited quantities for such purposes.

Vermiculite is also utilized in the manufacture of castable insulation products. For producing high-alumina vermiculite cement, a fast-hardening cement, alumina and lime are heated in a furnace to a high temperature. The product is ground to a powder, and vermiculite is added. Vermiculite cement can also be manufactured by combining it with Portland cement. Vermiculite cement is used in the production of ultra-lightweight aggregates for the construction industry (Table 13) and as lightweight insulation.

Vermiculite is utilized as a constituent in the manufacture of refractory blocks and fire bricks for use in furnaces up to 1200 °C.

In packaging technology, vermiculite is used to cushion impacts, for thermal insulation and to absorb liquids in case of breakage of the container.

Table 13. Physical properties of vermiculite lightweight concrete

Vermiculite/ cement ratio	Density, kg/m^3	Compression strength, N/mm^2	Thermal conductivity, $Wm^{-1}\,h^{-1}\,K^{-1}$	Shrinkage on drying, %
8 : 1	400	0.70	0.094	0.35
6 : 1	480	0.95	to	to
4 : 1	560	1.23	0.158	0.45

In metallurgy, it is used to cover molten metal for thermal insulation during intermediate storage prior to casting.

Expanded vermiculite is also used with garden and house plants to store water and plant nutrients (hydroculture), as a filter for swimming pools and for absorbing spilled liquids.

Economic Aspects. Total world production of crude vermiculite is ca. 512 500 t/a. Because of the short resources the production declined in the United States to ca. 177 000 t/a. Vermiculite is invariably expanded at a location close to the consumer to facilitate transport. The largest consumer country is the United States. European consumption is modest, most being imported from the Republic of South Africa. Although the total consumption of silicates used for thermal and acoustic insulation (including expanded perlite, hydrated and expanded broken glass, glass wool and rock wool) continues to increase, that of vermiculite is decreasing due to its comparatively high price.

2.10. Perlite

Perlite of rhyolitic composition is a natural, volcanic glass that is usually black or gray, but sometimes brownish red. It has curved shrinkage cracks and therefore breaks up into spheroidal granules. It is usually produced by rapid cooling of rhyolitic melts (rhyolite being the volcanic equivalent of granite). Being a volcanic glass, perlite contains few crystals and only a small amount of water (2 – 6 % combined water). Naturally-occurring glasses containing 3 – 8 % water are known as pitchstone (hydrated glass).

Perlite was first mined and expanded in 1946 in the United States. It has since been put to a wide range of uses in Europe. Thermally expanded perlite is increasing in importance as a lightweight filler in constructional units for thermal and noise insulation.

Composition varies according to the type of deposit:

SiO_2	72.0 – 76.0 wt %
Al_2O_3	11.0 – 17.0 wt %
K_2O	4.0 – 5.0 wt %
Na_2O	2.9 – 4.0 wt %
CaO	0.5 – 2.0 wt %
MgO	0.1 – 0.5 wt %
Fe_2O_3	0.5 – 1.5 wt %
TiO_2	0.03 – 0.2 wt %
MnO_2	0.03 – 0.1 wt %
SO_3	0 – 0.2 wt %
H_2O, chemically bound	2 – 7 wt %
Density	2.2 – 2.4 g/cm^3
Softening temperature	810 – 1090 °C
Melting temperature	1260 – 1340 °C
Specific heat	831 $J\,g^{-1}\,K^{-1}$
Bulk density, broken, classified	1.45 kg/L

The most significant variations are in water content, which has an important influence on the physical properties after expansion.

Deposits and Processing. The most important European deposits are found in Greece (Milos, Kos), Italy (Sardinia), Slovakia, Hungary, Bulgaria and Iceland. Further important deposits are located in Turkey (Cumaovasi, Izmir), Canada, Australia, Japan and the United States (New Mexico). Perlite is commonly extracted by open-cast mining. It is then crushed (usually by cone crushers) and classified using vibratory screens into several grain sizes with closely specified tolerances.

The industrial value of the classified ore depends on the temperature and time necessary for expansion, relative volume increase, ratio of closed to open bubbles (cells), nonexpandable fraction and compression strength of the product.

Expansion. Like vermiculite, perlite expands when heated, but in three dimensions. Expanded perlite has excellent insulation properties, comparable to those of vermiculite, which it can substitute to some extent. Expansion is performed in two types of furnace: (1) tilted

horizontal rotary furnaces through which the feed material passes in countercurrent flow to the combustion gas and (2) vertical rotary or blast furnaces through which the expanding grains and hot gases pass in cocurrent flow. Vertical expanders are more common. The expansion results from shock heating the grains to a temperature in the softening range (727 – 1127 °C), which results in bursting. Then the water bound in the perlite vaporizes and the heat-softened grains expand into light, cellular particles with up to 15 – 30 times the original volume. The cellular structure consists of numerous tiny, closed, thin-walled, glass-sealed air bubbles, which account for the excellent insulating properties of the expanded perlite. The optimum temperature – time profile must be closely followed. Longer heating times lead to shrinkage of the heated aggregates, and higher temperatures cause shrinkage and/or melting. The expanded material is classified in cyclones. In some cases, the expanded perlite is ground by pendulum or roller mills. If the product is to be used as a filler or additive, it is treated to make it hydrophobic; it may be silanized with dilute aqueous silane suspensions, or coated with dilute, aqueous silicone oil emulsions.

Quality. Important quality criteria for the expanded material include bulk density, ratio of closed to open air bubbles (cells), unexpanded fraction, and, if used as a filler, compression strength of the bulk material and binder requirement or water absorption properties. The bulk density of expanded perlite depends on the amount of chemically bonded water in the unexpanded material and on the temperature – time profile used for expansion and can be 0.03 – 0.2 kg/L. The fraction of the material with open cells and the fraction of nonexpanded grains should not exceed 5 %. These parameters are both determined by a water-immersion test using material that has not been rendered hydrophobic.

Properties. The most important properties for the diverse applications of expanded perlite are its extremely low density, low thermal conductivity, low thermal expansion, good sound absorption, adequate compression strength at a bulk density of > 0.1 kg/L, and resistance to acids, weathering, and microbial attack. The average properties of industrial perlite (from Milos) after expanding and grinding to 98 % < 40 µm are given below:

Refractive index	1.49
Brightness index Ry (according to DIN 53 163)	82 – 85
Bulk density	0.080 kg/L
Tamped density	0.240 kg/L
Oil absorption number (standard grade)	500 – 600 g/100 g
Water absorption number (standard grade)	400 – 500 g/100 g
Water absorption number (hydrophobic grade)	20 – 25 g/100 g
pH	8 – 9
Thermal expansion coefficient (0 – 100 °C)	0.007 K^{-1}
Thermal conductivity (25 °C)	
Bulk density	
0.04 kg/L	0.04 $W\,m^{-1}\,h^{-1}\,K^{-1}$
0.09 kg/L	0.05 $W\,m^{-1}\,h^{-1}\,K^{-1}$
0.13 kg/L	0.06 $W\,m^{-1}\,h^{-1}\,K^{-1}$
Thermal conductivity (bulk density 0.09 kg/L)	
20 °C	0.05 $W\,m^{-1}\,h^{-1}\,K^{-1}$
400 °C	0.11 $W\,m^{-1}\,h^{-1}\,K^{-1}$
800 °C	0.22 $W\,m^{-1}\,h^{-1}\,K^{-1}$

When perlite is used as a filler and as an additive to lightweight concrete, very high compression strength and resistance to abrasion are required during mixing. These grades have higher densities (0.12 – 0.14 g/L) and are produced from rhyolitic rock.

Uses. Expanded perlite is used as an ultralightweight aggregate in the construction industry and as lightweight insulation. The most important uses of expanded perlite (normally treated to render it hydrophobic) include loose-fill insulation, filled plaster board and wall elements, insulating silicate-bonded boards for thermal and flame protection, insulating bitumen-bonded boards for back facing, insulating boards and coating materials with polymer binders, mortar (bonded with cement, plaster, or silicate), polymer dispersion mortars and plasters for thermal insulation and prevention of condensation on walls and ceilings (e.g., in swimming pools and high humidity rooms).

Coarse-grade expanded perlite (2 – 5 mm) is used in metallurgy to limit the loss of heat from molten metal surfaces. A fine grade (0.15 – 1.8 mm) is used as a thermal insulator in cryogenic applications. In cryogenic applications, expanded perlite is normally uses unfer vaccum conditions.

Expanded perlite, with a bulk density of 0.04 – 0.06 kg/L, is used as an adsorptive filtering aid in precoated filters (e.g., for drinking water or medicinal products).

Economic Aspects. Next to the United States, Western Europe is now the largest consumer of perlite. World annual production of raw perlite is estimated to be ca. 1.8×10^6 t. In Germany ca. 100 000 t/a perlite is expanded, of which ca. 70 000 t (corresponding to ca. 580 000 m^3) is used as a raw material for the building industry. The amount of perlite (from Italy, Greece and Iceland) expanded in the United Kingdom is > 120 000 t/a. The total for France is ca. 90 000 t/a.

2.11. Pumice

Pumice [*001332-09-8*] is not a crystalline silicate mineral, but a light-colored, highly vesiculated, foamed volcanic glass of mainly acid character (> 66 % SiO_2, rhyolite), with a high melt viscosity, high pore volume (> 50 %) and variable water content. Rhyolite itself is an acid volcanic rock consisting of feldspar, quartz, biotite, etc. and glassy groundmass. By rapid undercooling (quenching) of rhyolitic magma, volcanic rocks are produced which consist completely or almost completely of volcanic glass, named obsidian (containing less than 1 wt % H_2O and composed of more than 80 wt % of volcanic glass including mostly very negligible amounts of minute inclusions of quartz, tridymite, feldspar, fayalite, etc.) or pumice, the latter highly vesiculated. Volcanic lava of rhyolitic composition releases enclosed gases (water vapor, carbon dioxide, nitrogen, sulfur dioxide, chlorine, etc.) at ca. 1000 °C explosively as a result of an abrupt pressure drop forming bubbly pumice. Due to its high porosity, pumice is very light and floats on water.

The specific heat capacity of pumice is 1.00 J g^{-1} K^{-1} and its thermal conductivity at 50 °C is 0.274 W m^{-1} h^{-1} K^{-1}.

Crushed and classified pumice is employed as an additive in light insulating concrete used to make constructional units. Due to its limited compression strength, this building material can only be used for one- or two-storey buildings or for cladding load-bearing frameworks. The specific heat capacity of pumice concrete is 1.005 kJ kg^{-1} K^{-1} and its thermal conductivity is 0.457 W m^{-1} K^{-1} for a density of ca. 1.1 kg/L.

Building blocks (e.g., Bisotherm, Bisothermwerke Carl Riffer, Urmitz) consist of pure, natural pumice granules treated to remove organic and inorganic impurities. Denser inorganic impurities such as fragments of obsidian and lavastone are removed by air separation and organic impurities by calcining at ca. 400 °C in rotary kiln (DIN 18 151, 18 152). They are mainly used to build houses.

Pumice in different industrial grades has a wide range of applications: stonewashing of denim and cotton, in agriculture (soil substitute, additive), paint manufacture (non-skid coatings, acoustic insulating ceiling paints, fillers for textured paint), chemical industry (filtration media, chemical carriers, pesticide carriers), cleaning and polishing of metals and plastics, compounders (powdered hand soaps, glass cleaners), dental and cosmetic (polishing natural teeth and dentures, smoothing rough skin), rubber (erasers, mold-release agents), glasses and mirrors (TV tube processing, glass buffing and polishing), furniture (hand-rubbed satin finishing, piano keys, picture frame gold leafing), leather (buffing), electronics (cleaning circuit boards) and pottery (filler).

Powdered pumice is used as an abrasive, as a polishing medium, as an antiskid material and as an additive to pumice soap. It is also used as an absorption medium due to its large surface area (e.g., in packages carrying breakable liquid containers).

As an insulator, pumice competes with expanded perlite (see Section 2.10) and expanded, exfoliated vermiculite (see Section 2.9).

The output of pumice in Germany is ca. 2.4×10^6 t/a, worldwide ca. $6.5 - 7 \times 10^6$ t/a.

Important commercially exploited pumice deposits occur in Germany (Koblenz-Neuwied district), in Italy (isle of Lipari – northeast to Sicily, and around Naples), on volcanic Greek islands (Dodecanese group: islands of Yali and Nisyros, Cyclades group: Thera Island), in Spain (Province of Ciudad Real, Canadas area on isle of Tenerife), Portugal (on the volcanic island of Sao Miguel in the Azores), the United States (in central New Mexico in the area of Santa Fe, at Gate in Oklahoma, and in Idaho and California),

on Caribbean islands (Dominicana, Martinique), on volcanic islands of Japan (southern parts of Hokkaido and Kyushu), and in New Zealand (North Island).

2.12. Basalt

Basalt is the most common volcanic rock, occupying large areas of the Earth's surface (e.g., plateau basalt). It contains $< 52\,\%$ SiO_2 and is the volcanic equivalent of the gabbro rock family. Basalt has a dense, compact, sometimes granular or porphyric structure and is dark to black in color. The main constituents of the matrix are plagioclase (anorthite 50 – 75 %) and pyroxene (mainly augite). Accessory minerals include olivine, magnetite, ilmenite, alkali feldspar, alkali pyroxene, alkali amphibole, feldspathoids and volcanic glass. Basalts are worldwide by far the most extensive exposed crustal igneous rocks, and their formation can be observed even now (e.g., numerous volcanoes in Asia, the United States, Europe and at the mid-ocean ridges).

The most important types are the tholeiitic basalts (often associated with some olivine and, when supersaturated with SiO_2, even quartz) and the alkali basalts (feldspathoids, alkali pyroxene, alkali amphibole and olivine). Medium- to coarse-grained basalts are known as *dolerites,* while olivine basalts (which contain feldspathoids as well as plagioclases) are known as *basanites,* and anchimetamorphic basalts of the Permian/Carboniferous era are known as *melaphyres, diabases* and *greenstones.*

The largest single basalt mass in Europe is in the Vogelsberg region of Germany. Other large deposits are in Hegau, the Eifel, the Westerwald and the Rhön mountains. Another deposit extends from the Oberpfalz (Bavaria), through the Erzgebirge and as far as the Lausitz region.

Some basalts have high strengths and are therefore used in the construction industry, e.g., as hard core, paving stones and building materials. In another important application, molten basalt is converted into refractory fibers (mineral wool for insulation and fire protection) (→ Fibers, 5. Synthetic Inorganic, Chap. 2.2.).

The physical properties required depend on the use intended for the basalt. These include high compression strength (2500 – 4000 kg/cm^2, with a maximum of 5800 kg/cm^2) and transverse strength (150 – 250 kg/cm^2, DIN 52 100). It should be as homogeneous as possible and should be resistant to frost, acids and waste gases (e.g., flue gas). The shapes of the naturally-occurring blocks of material also influence possible uses, e.g., columnar masses with polygonal cross sections, having 4 – 7 sides (feldspar basalts).

The density of basalt varies between 3.00 and 3.15 g/cm^3, the bulk density between 2.95 and 3.00 g/cm^3 and the bulk density of basalt lava between 2.20 and 2.35 g/cm^3. The porosity of basalt varies between 0.2 and 0.9 vol %, and of basalt lava between 20 and 25 vol %. Thus, the water absorption of basalt varies between 0.1 and 0.3 wt %, and of basalt lava between 4 and 10 wt %. The specific heat capacity (0 – 770 °C) is ca. 1.09 J g^{-1} K^{-1}, and the thermal conductivity (0 – 100 °C) is ca. 0.028 W cm^{-1} K^{-1}. The linear expansion coefficient is ca. 9×10^{-6} K^{-1}. Anhydrous basalt begins to melt at ca. 1280 °C, but at only ca. 1100 °C if it contains 1 % water. Basalt wool is stable up to 900 °C.

Sunburnt basalt is unsuitable for many applications. It is affected by weathering very soon after it is mined, especially by the heat of strong sunlight in the presence of moisture. Characteristic white spots are formed, and the rock crumbles. This phenomenon is not limited to basalts alone, but can also occur with other effusive rocks (e.g., phonolite). The "sunburning disease" of basalt is probably mainly due to the conversion of nepheline into analcime ($Na[AlSi_2O_6] \cdot H_2O$), which is accompanied by a volume increase of ca. 5.5 %.

2.13. Wollastonite

Wollastonite [*013983-17-0*], $Ca_3[Si_3O_9]$, is polymorphic. Three modifications occur naturally, the commonest being low wollastonite which has two polytypical structural modifications: triclinic wollastonite (-1T) and monoclinic wollastonite (-2M, parawollastonite).

Structure and Mineralogy. In monoclinic wollastonite, the $[SiO_4]$ tetrahedra are linked to form infinite one-dimensional dreier single chains of $[Si_3O_9]^{6-}$ units (Fig. 29). These are bonded together by Ca^{2+} ions (which balance

the electrical charge), and the chains lie parallel to b [010]. This explains why the crystals are always extended in the direction of b [010]. The monoclinic structure is derived from the triclinic by "inner twinning" on the (100) plane. Wollastonite (-1T) and wollastonite (-2M) are therefore inosilicates (silicates containing $[SiO_4]$ tetrahedra in infinite chains).

Figure 29. Basic configuration of $[SiO_4]$ tetrahedra in the infinite one-dimensional dreier single chains $[Si_3O_9]^{6-}_{\infty}$ of wollastonite, $Ca_3[Si_3O_9]$

Cyclowollastonite (high wollastonite or pseudowollastonite) is a cyclosilicate and is stable above 1126 °C. The $[SiO_4]$ tetrahedra are arranged in three-membered rings $[Si_3O_9]^{6-}$, which are linked together and neutralized by Ca^{2+} ions (Fig. 30). High-pressure $Ca_3[Si_3O_9]$ also contains rings of tetrahedra.

Figure 30. Basic configuration of $[SiO_4]$ tetrahedra in the dreier single rings of $[Si_3O_9]^{6-}$ of cyclowollastonite, $Ca_3[Si_3O_9]$

Wollastonite (-1T), $Ca_3[Si_3O_9]$, forms triclinic – pinacoidal crystals, with space group C_i^1 – P 1, and has the following lattice constants: $a_0 = 0.794$ nm, $b_0 = 0.732$ nm, $c_0 = 0.707$ nm; the axial ratio is $a_0 : b_0 : c_0 = 1.084 : 1 : 0.966$; $\alpha = 90°02'$, $\beta = 95°22'$, $\gamma = 103°26'$; $Z = 2$.

Wollastonite (-2M), (parawollastonite), $Ca_3[Si_3O_9]$, forms monoclinic – prismatic crystals, with space group C_{2h}^5 – $P\,2_1/a$; lattice constants: $a_0 = 1.536$ nm, $b_0 = 0.729$ nm, $c_0 = 0.708$ nm; the axial ratio is $a_0 : b_0 : c_0 = 2.107 : 1 : 0.971$; $\beta = 95°24^1/^2{}'$; $Z = 4$.

Cyclowollastonite (high wollastonite, pseudowollastonite), $Ca[Si_3O_9]$, forms triclinic – pseudohexagonal crystals ($b{:}a = 1.707 \approx \sqrt{3}$); lattice constants: $a_0 = 0.690$ nm, $b_0 = 1.178$ nm, $c_0 = 1.965$ nm;
the axial ratio is $a_0 : b_0 : c_0 = 0.586 : 1 : 1.668$; $\alpha = \gamma = 90°$, $\beta = 90°48'$; $Z = 8$.

High-pressure $Ca_3\,[Si_3O_9]$ forms triclinic crystals with lattice constants $a_0 = 0.6695$ nm, $b_0 = 0.9257$ nm, $c_0 = 0.6666$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.723 : 1 : 0.720$, $\alpha = 86°38'$, $\beta = 76°08'$, $\gamma = 70°23'$.

In natural wollastonite, Ca^{2+} can only be substituted to a very small extent (ca. 1 – 2 atom %) by Mg^{2+}, Fe^{2+} and Mn^{2+}. Alternatively, it can be substituted by 2 wt % Al_2O_3.

In the wollastonite (-1T) found in industrial products, (β-$Ca_3[Si_3O_9]$), Ca^{2+} can be substituted by Fe^{2+} up to 70 wt % $FeSiO_3$. In industrial cyclowollastonite, (α-$Ca_3[Si_3O_9]$), Ca^{2+} cannot be substituted by Fe^{2+}, but can be substituted by Mn^{2+} up to 1 – 2 atom % and by Sr^{2+} over the entire concentration range.

Wollastonite is usually intergrown and well-formed crystals are very rare. It occurs mostly in the form of thick plates parallel to {100} and {001} and is always extended on the b axis [010]. It is often found in coarse masses, in flat, thin, divergently radiating masses, or in stalked, spiky, tabular, lamellar or finely fibrous aggregates and masses.

Magmatic formation of wollastonite is possible where the magma resorbed calcium while in contact with limestones. This mineral is found in some alkaline igneous rocks and in phonolites, andesites, etc. Wollastonite is commonly a product of contact metamorphism, and sometimes also of regional metamorphism. Under the conditions of contact metamorphism, wollastonite is formed at high temperatures from quartz and calcite in siliceous limestones and by SiO_2 metasomatism in pure limestones. Cyclowollas-

tonite is only rarely found in metamorphic rocks (e.g., south-west Iran, Kropfmühl near Passau in Bavaria).

Cyclowollastonite is formed when wollastonite is heated to $>1126\,°C$. It melts congruently at 1544 °C. In industrial products, cyclowollastonite is the modification that is most often formed, e.g., in silicate bricks, in blast furnace slags and their reaction products with silicate bricks, in slightly basic open-hearth slags, or as a devitrification product in high-calcium bottle glasses.

Properties. The physical properties of interest for industrial applications are given in Table 14. Wollastonite is usually white, translucent and sometimes pale greenish, bluish or brownish. It has a vitreous luster, a nacreous luster on fractured surfaces and coarse masses, and a silky luster in fibrous aggregates. Cleavage is perfect on (100) and (001) and well developed but variable on $(\bar{1}01)$ and $(\bar{2}01)$. The Mohs hardness is 4 1/2 – 5 and the density 2.8 – 2.9 g/cm^3.

Cyclowollastonite usually forms irregular grains and is colorless, with cleavage on (001). The Mohs hardness is 5 and the density 2.91 g/cm^3.

The lower limit of transparency to UV light is at $\lambda = 290$ nm. Wollastonite shows a yellowish thermoluminescence at moderate light intensities. The phosphorescence is yellowish-white and is intensified by doping with 0.5 wt % Nd_2O_3. Cathodic luminescence is influenced by vacuum, temperature and additives.

The electrical conductivity at 1300 °C is $0.18\,\Omega^{-1} \cdot cm^{-1}$ and the dielectric constant at 20 °C is 6.17.

The ideal chemical composition for $CaO \cdot SiO_2$ is 48.29 wt % CaO, 51.71 wt % SiO_2. Aqueous mineral acids decompose wollastonite and pseudowollastonite, producing gelatinous SiO_2. Alkaline solutions do not attack it. It is resistant to weathering and industrial atmospheres.

Production. Pseudowollastonite (cyclowollastonite) is produced industrially as a sintered phase by a diffusion reaction:

$$CaO + SiO_2 \xrightarrow{1400\,°C} Ca[SiO_3] \text{ or}$$
$$CaCO_3 + SiO_2 \xrightarrow{1550\,°C} Ca[SiO_3] + CO_2$$

The reaction is accelerated by the addition of mineralizers (e.g., 1 wt % NaCl, Na_2WO_4 or CaF_2). The solid-state reaction between CaO and SiO_2 is also accelerated in the presence of water vapor.

Finely ground CaO and SiO_2 are melted together in the molar ratio 1 : 1, the melt is then rapidly cooled to form a glass, and the vitreous product is then heated to 800 – 1000 °C.

Deposits and Processing. Although wollastonite (-1T) and wollastonite (-2M), which is somewhat rarer, are widely distributed, in the past only a few deposits were extracted economically up to the 1980s, when the demand for wollastonite and its production increased and doubled in less than 10 years. The most important deposits are in the United States (Willsboro and Harrisville in the State of New York, Riverside in California, Tonopah in Nevada), China (Meiyaoshan and Tiengongshan in Jilin province, Fulapu and Shijianfang, near Faku in Liaoning province, Xinyu in Jiangxi province, Daye in Hubei province, Changxing in Zhejiang province, Qinghai province), India (Belka in the Sirohi District, Kheratarala in Udaipur District), Finland (Lappeenranta), along with Mexico (La Blanca and Panfillo Natera in Zacatecas State), Chile, Namibia (Usakos), Kenya (Kajiado), Turkey, Pakistan, North Korea, Russia, Canada, Spain, Greece, Morocco, New Zealand and Cuba.

In the Willsboro mines, the rock contains ca. 60 % wollastonite (-1T) and (-2M), ca. 40 % almandine, and some diopside. It is crushed in three stages to < 16 mesh (1.2 mm). The almandine is then removed by magnetic separators. The wollastonite concentrate is finally ground and classified by air elutriation.

The rock from Lappeenranta contains an average of 20 % wollastonite (-1T) and (-2M) and accompanying minerals: calcite, dolomite, and quartz. Treatment consists of wet grinding (rod mills), classification (hydrocyclones), flotation (the wollastonite becomes concentrated at the bottom of the flotation cell), magnetic separation of the wollastonite concentrate, filtration and drying. The finished product consists of 90 % wollastonite, 4 % quartz, 4 % calcite and 2 % other silicates.

Table 15 gives the chemical composition of commercial wollastonite products. Table 14

gives the physical properties of Finnish wollastonite (-1T) and (-2M).

Uses. Wollastonite is widely used in ceramics, plastics, asbestos substitution, metallurgy, paints and glass manufacturing. Wollastonite is classifed into high aspect ratio wollastonite and milled or powdered wollastonite. High aspect ratio wollastonite has an aspect ratio of 1:10 to 1:20 and is well suited as a reinforcing functional filler in plastics, rubber, paints, and coatings and as an asbestos substitute. In these applications, wollastonite is characterized by enhanced hardness, flexural strength, and impact resistance, and also improves the electrical properties and the thermal and dimensional stability of plastics. Milled or powdered wollastonite is used as a filler in ceramics and in metallurgy. The milled wollastonite grades are cheaper than the high aspect ratio grades.

The highest volume use of high-grade wollastonite, i.e., modifications (-1T) and (-2M), is as a raw material for *ceramic products* (see Tables 15 and 16). Teh considerable increase in use o wollastonite can be attributed to the spread of fast-firing techniques, significantly reducing the consumption of energy and improving productivity. Its important advantages include its lack of chemically bonded water (which could break down the structure and even cause explosions during firing), the ease of water removal on drying via the capillaries associated with its acicular (i.e., needle-like) crystal structure, the low shrinkage on drying and firing, the very low coefficient of expansion, the fairly low melting point, the mechanical strengthening of the "green" molded articles due to the acicular structure present until firing and the high breaking strength and thermal shock resistance of the finished product. The high lightness value (see Table 16), which is maintained after firing, enables wollastonite (-1T) and (-2M) to be used in the production of neutral, white ceramic products (e.g., white tableware). The raw material mixture should contain 20 – 50 % wollastonite. Other uses include wall and floor tile bodies and glazes, sanitary ware, earthenware, frits, frit

glazes, and porcelain enamels and specialized applications.

Table 16. Physical properties of Finnish wollastonite (-1T) and (-2M)

Property	FW 200	FW 325

∗ Tristimulus value *Y* measured with standard illuminant according to DIN 5033, color temperature 2856 K, ca. 546.1 nm using ELREPHO equipment.

The addition of wollastonite to frits for ceramic glazes and enamels reduces the firing temperature and the formation of hairline cracks and helps stop cracking, crazing, breaking and glaze defects. It also improves surface hardness and luster. Blister formation due to outgassing of volatile constituents is also reduced. Wollastonite added in amounts of 1 – 3 % to flint and/or flux reinforces semivitreous products and decreases shrinkage and moisture expansion. In some other ceramic applications, feldspar and quartz are substituted by 2 – 5 % wollastonite in vitrified bodies to lower vitrification temperatures and to decrease shrinkage.

The (-1T) and (-2M) modifications are preferred for use as fillers in industrial chemical products and plastics. The chain structure of the lattice leads to the formation of acicular crystals and short fibers, which impart structural viscosity both to molten thermoplastics and to coating materials (paints, plastisols, etc.) and improve the mechanical properties of the solid matrix. In polymer emulsion paints, texture paints, plasters and putties, addition of wollastonite improves abrasion resistance and weathering resistance and reduces shrinkage cracking.

The *plastics* industry is a major consumer of wollastonite. In plastics most grades of wollastonite can be utilized, but most significant are those with high aspect ratio, fine and surface-coated grades. Wollastonite is used in both thermoplastics (polyamides, polyesters, liquid crystal polymers and engineering resins) and thermosets (phenolic molding compounds, epoxies, polyurethanes, polyurea and unsaturated polyesters). Typical loadings of wollastonite in plastics are: nylon 50 %, low-density polyethylene 40 %, polypropylene 23 – 28 % and polystyrene 30 %. A further important market for wollastonite is automotive plastics, in which it acts chiefly as a reinforcement, e.g., in reinforced reaction injection molded components.

In *paints and coatings* high aspect ratio wollastonite is used as a reinforcing filler. In paint films, wollastonite improves the mechanical strength, durability and resistance to weathering, cracking and other ageing effects. Wollastonite has a pH of 9.9 in water and hence functions as an effective alkaline buffer in latex paints, preventing destabilization due to pH drift, particularly when acidic pigments and extenders such as kaolin and aluminum silicate are utilized.

Acicular wollastonite can be mixed with mineral filler materials exhibiting platelet-shaped, lamellar particle shapes (kaolinite, mica, talc, and pyrophyllite) to give filler mixtures with desirable rheological working properties (e.g., adjustable thixotropy).

Wollastonite is an important substitute for short-fiber asbestos and is used widely in reinforcement applications, in fire-resistant wall board and cement products and friction products (brake pistons, brake linings, clutches etc.).

In metallurgical applications the low temperature fluxing of wollastonite imparts better surface finish in continuously cast steel and inhibits sparking in welding.

Due to its luminescent properties, wollastonite, especially the synthetic variety, is the base material of many phosphors, whose characteristics can be varied by doping with heavy metal and rare earth ions.

Synthetic wollastonite is used in synthetic bone implants, to replace bone loss and as a vertebral prosthesis in medical cases requiring load-bearing capacity. Synthetic wollastonite quickly forms strong, biologically safe bonds with osseous tissue.

The favorable electrical properties of wollastonite (high volume resistance and surface resistance, low dielectric loss angle) lead to its use

as an additive to electrical insulating paints and casting materials.

Acicular wollastonite particles can be mixed with filler materials with platelet-shaped particles (kaolinite, mica, talc and pyrophyllite) to give filler mixtures with desirable rheological working properties (e.g., thixotropy that can be adjusted).

The most important producers and suppliers of natural and synthetic wollastonite are the NYCO Minerals Corporation (Willsboro, New York, United States) and the Partek Industrial Minerals Oy (Lappeenranta, Finland). World production of natural wollastonite is estimated at 365 000 t/a. Of the 120 000 t/a of wollastonite that is expected to be produced in the United States, some 90 000 t is consumed by the domestic market and the surplus is exported mainly to Europe. The production of natural wollastonite by Mexican producers is estimated to be 30 000 t/a, by Indian ca. 60 000 t/a, by China 120 000 t/a, and by Finnish producers ca. 30 000 t/a. The European consumption is estimated to be well over 70 000 t/a, of which ca. 65 % is used in the ceramics industry.

2.14. Toxicology

Most of the silicates described in Chapter 2 are not known to be toxic or carcinogenic. However, the inhalation of fine particles ($< 5\,\mu m$, fibrogenic dusts) of silicates and hydrated silicates which have an acicular or fibrous morphology and are insoluble in the environment inside the lungs (pH < 7) should be filtered out by means of effective industrial dust-removal equipment or respiratory protection masks.

The MAK values for inert granular and platelet-shaped silicate dusts is set at 6.0 mg/m^3 in view of possible effects on the respiratory organs. This figure applies to exposure to the dust for one year, or, if each individual exposure to dust is known and documented, for a total exposure time of one year spread over a period of five years.

In the case of exposure to fine wollastonite dust (respirable dust $< 5\,\mu m$), respiratory protection is recommended. It is not yet known whether there is a health hazard from the inhalation of cyclowollastonite dust. However, respirable wollastonite (-1T) and (-2M) dusts are suspected to be carcinogenic.

3. Alkali Silicates

3.1. Introduction

Historical Aspects. The solubility in water of a fused mixture of flint pebbles with potash was first described by the Brussels physician Jean Baptiste van Helmont (1577 – 1644) in his posthumous work "Ortus medicinae", Amsterdam 1648.

Independently, Johann Rudolph Glauber (1604 – 1670) studied the properties of a "thick" solution that he obtained from a fused mixture of sand, flint pebbles, or crystalline quartz with potash, and named "Liquor Silicum". He recommended its use as a curative agent, for the production of liquid fluxes in metal smelting, and for glazing earthenware vessels (Furni Novi Philosophici, Amsterdam 1648 – 1650).

In 1768, during the course of his alchemical studies, Goethe became interested in potassium silicate [116].

Although there were many later reports, the water-soluble silicates were seldom put to practical use until about 1825 when Johann Nepomuk von Fuchs in Munich investigated the industrial production of water-soluble potassium and sodium silicates, which he named "waterglasses" (i.e., water-soluble glasses), and proposed that their solutions might be used as adhesives, for sealing porous stone, and as binders for fresco painting [117]. He exchanged ideas with Justus von Liebig and C. F. Kuhlmann. The latter first produced waterglass in France in 1841 [118, 119]. Soon afterwards, similar work was undertaken in England by W. Gossage, and in various parts of the United States [120].

Waterglass was more widely used during the course of the American Civil War (1861 – 1865), when the northern states utilized it in soap manufacture as a replacement for rosin formerly obtained from the southern states.

Definitions. Commercial alkali silicates are generally specified according to:

1) *Source of alkali* (soda, potash, lithia).

2) *Ratio of silica to alkali-metal oxide.* The usual ratio given is the weight (wt %) ratio or modulus, R_W. The equivalent molar ratio, R_M, can be more useful, particularly when comparing ratios of potassium and sodium silicates. For sodium silicates, the conversion factor is $R_M = 1.032\,R_W$, while for potassium silicates, $R_M = 1.568\,R_W$.
3) *Water content of the silicate.* For solid, crystalline silicates, this corresponds to the water of crystallization. For example,sodium metasilicate, $Na_2O \cdot SiO_2$, can be prepared in anhydrous form, or as the pentahydrate or nonahydrate [121]. Amorphous alkali silicate glasses are essentially anhydrous. The water content of silicate solutions is customarily defined indirectly by giving the density of the solution, which together with the silica to alkali-metal oxide ratio, defines a unique composition for the silicate solution.

Solid alkali-metal silicates used in industry are divided into two groups:

1) Water-soluble silicates solidified as a glass from a melt, normally containing ca. 1.5–4 mol SiO_2/mol M_2O (Section 3.3). These silicates and their aqueous solutions are commonly referred to as waterglass (solid glass or liquid glass). The most common commercial products are concentrated waterglass solutions, which are usually produced by dissolution of silicate glasses in water or by direct dissolution of sand in sodium hydroxide (see Section 3.4).
2) Solid, crystalline sodium silicates, often with water of crystallization. Commercial products of this type are known for $Na_2O \cdot n\,SiO_2$, where $n = 0.5$ (orthosilicate), 1.0 (metasilicate), and 2.0 (disilicate) (see Section 3.6).

3.2. Raw Materials

The dominant silica component used in industry is quartz sand (grain size 0.1–0.5 mm) which has been washed to remove clays and other impurities. The most problematic impurity in such sands is iron, normally present to the extent of ca. 300 ppm. To obtain extremely pure alkali silicates, mainly for scientific use, very finely divided, very pure silica (e.g., fume silica such as Aerosil) is recommended. The alkali-metal oxides are provided in the form of their carbonates or hydroxides. The purity of the starting materials is dictated by the purity requirements for the end products.

An appropriate sulfate may also be used as a cheap source of alkali in silicate production, but requires the presence of a reducing agent (normally coal dust). Very little sulfate-derived glass is produced because the melting process is longer and this, together with the presence of sulfur oxide gases, increases corrosion of the furnace walls. In addition, residual alkali sulfate and ash from the coal result in a relatively impure product.

3.3. Amorphous Anhydrous Alkali Silicates (Solid or Lump Glasses)

Properties. Sodium and potassium silicate glasses are prepared commercially as glass lumps or powders. They are normally colored owing to the presence of impurities, the most usual colors being blue to green or yellow-brown caused by the presence of di- or trivalent iron, respectively.

Alkali silicate glasses with compositions close to those of stoichiometric compounds (e.g., $Na_2O \cdot 2\,SiO_2$, $K_2O \cdot 2\,SiO_2$, $K_2O \cdot 4\,SiO_2$) can be made to crystallize by holding them just below their melting points for long periods. In general, however, commercial alkali silicates are not stoichiometric compounds. Instead, their molar ratio, SiO_2/M_2O, usually fluctuates around average values at which stable solutions can be obtained (Table 17). The vast majority of commercially produced alkali silicate glass is sodium silicate. Furthermore, sodium silicate liquors with a wide range of R_W values may be produced by blending two different liquors with each other or with alkali hydroxide. Virtually all commercial glass production is of sodium silicate of $R_W = 2.0$ (alkaline glass) or $R_W = 3.3$ (neutral glass) [122]. A smaller amount of potassium silicate glass is manufactured and is normally restricted to the ratios $R_W = 2.5$ and $R_W = 2.0–2.1$. Lithium silicate glasses are not readily watersoluble and hence are not produced on a commercial scale [123].

Figure 31. $SiO_2 - Na_2O$ system

The structure of silicate glasses is based on tetrahedral SiO_4 groups that are associated as polysilicate anions by sharing corners of the tetrahedra. The environment of a single Si atom is referred to as Q^n, where n is the number of shared corners for the tetrahedron [124]. The structures of the glasses are discontinuous, with SiO_2-rich domains separated by clusters of M^+ ions.

Figure 32. $SiO_2 - K_2O$ system

The melting points of the solid silicates may be obtained from the liquidus diagrams of the systems $SiO_2 - Na_2O$ and $SiO_2 - K_2O$ (Figs. 31 and 32).

Sodium silicates with $R_W \geq 3$ are only slightly attacked by water at room temperature. Sodium silicates with $R_W = 2$ are hygroscopic and cake on storage in moist air. At equivalent molar ratios, potassium silicate glasses are more hygroscopic than their sodium counterparts – potassium silicate of $R_W = 2.0$ ($R_M = 3.1$) also cakes in contact with moist air. Addition of a large excess of hot water to silicate glass causes hydrolysis and leaches out some of the alkali [125]. This alkali then attacks the residual silica, causing dissolution. Solid silicates can be dissolved at temperatures in the region of the boiling point in concentrated circulating solution, but silicate solutions are almost invariably produced by operating at pressure.

Production. Mixtures of pure silica sand (glass sand) and alkali carbonate in the required ratio are continuously fed by a cooled screw conveyor into furnaces that are regeneratively heated by oil or gas. The raw material ratio must allow for losses of alkali carbonate due to vaporization and attack on the material of the furnace. The temperature of the gas space is ca. 1600 °C, the final melt temperature being 1300 – 1500 °C. The carbon dioxide is driven off by reaction of the metal carbonate with the silica:

$$M_2CO_3 + nSiO_2 \longrightarrow M_2O \cdot nSiO_2 + CO_2$$

The furnaces are all of similar construction and size (capacity 150 t) to those used in the glass industry (→ Glass, Chap. 5.2.). They must be lined with high-quality refractory bricks (e.g., sillimanite) since the alkaline melts are very aggressive. The melt flows through the furnace and leaves continuously via an overflow into small molds which are moved along in an endless chain. The cast pieces (diameter ca. 8 cm, thickness 1 – 2 cm) cool as they are transported and often shatter.

Silicates are also produced in a batch process in small furnaces or continuously in rotary furnaces.

The cast blocks of silicate glass are dissolved in water while still warm or after intermediate storage (see Section 3.4). For some applications, they are ground and sieved.

3.4. Silicate Solutions

Properties. Solutions of sodium and potassium silicates with $SiO_2/M_2O \geq 1.5$ are colorless, water white, and viscous. The viscosity increases with concentration and, for a given constant silica content, with the SiO_2/M_2O ratio. When a critical concentration is reached, it rises very rapidly with further concentration (see Fig. 33). For a given ratio there is a limiting concentration above which the solution becomes either too viscous or too unstable for industrial use.

Figure 33. Change of viscosity with density at constant $SiO_2 : Na_2O$ ratios

The structures of the silicate solutions have been probed by a wide variety of techniques such as IR/Raman spectroscopy, light scattering, and chromatography [126–130]. The most valuable techniques are, however, trimethylsililation and ^{29}Si-NMR [129, 131–133]. Alkali silicate solutions contain, in addition to Me^+, OH^-, and orthosilicate ($H_xSiO_4^{(4-x)-}$) ions, a wide variety of linear, cyclic, and highly cross-linked polysilicate ions. The degree of polymerization of the silicate ions increases with increasing concentration and increasing ratio of the solution. Relatively small polysilicates (≤ 8 Si atoms) can be identified by comparing their silylated derivatives with derivatives of known structures from silicate minerals [134]. In addition, ^{29}Si-NMRalso allows identification of oligomeric silicate ions in dilute solutions [131–133]. In more concentrated solutions, however, and particularly at high ratios, NMR signals of individual species cannot be observed, peaks in the NMR spectrum then correspond to the Q^n species (see Section 3.3) [135]. This is illustrated in Figure 34, which shows ^{29}Si-NMR spectra for sodium silicates of $R_W = 2.0$ and 3.3 at typical commercial concentrations. The spectrum of the material with $R_W = 2.0$ is dominated by silicons of the Q^2 type, indicating a preponderance of small cyclic or linear silicate ions; in the material with $R_W = 3.3$, on the other hand, more than 50 % of the silicon atoms are present as Q^3 or Q^4 species, indicating a higher level of three-dimensional, branched polysilicates. These large polysilicate anions are mainly responsible for the high viscosity of silicate solutions. The silicate anions are in dynamic equilibrium and addition of alkali hydroxide (tantamount to reducing the ratio) causes hydrolysis of the polysilicates, thus reducing the viscosity, although even highly alkaline silicate solutions still contain polysilicates. Extensive dilution with CO_2-free water also depolymerizes the polysilicate anions. A wide variety of silicate solutions are available commercially. Sodium silicates are marketed with R_W ranging from 1.5 to 3.85, while potassium silicates are available with R_W from 1.43 to 2.48. Lithium silicates are also available commercially. Table 18 gives physical data for a few typical commercial silicate solutions, while Table 19 lists typical composition ranges for a commercial sodium silicate ($R_W = 3.3$).

All silicate solutions are highly alkaline. Dilution reduces the pH, but less than might be anticipated owing to the buffering action of the silicate. For example, dilution of Crystal 79 ($R_W = 3.3$, 25 wt % silica) to a 1 wt % solution reduces the pH from 11.6 to 10.8.

Addition of acids and acid salts (including carbon dioxide and bicarbonates) to silicates liberates silica. This is the basis of the industrial preparation of silica sols, silica gels, and precipitated silicas, the type of silica being formed depending on the concentration, temperature and

Figure 34. ^{29}Si-NMR spectra for sodium silicates
A) Crystal 100 A; B) Crystal 79

salt content of the solution (→ Silica) [122, 136]. Salts of polyvalent cations yield mixtures of silica gel with metal hydroxide [123]. Well-defined silicates are usually formed only after prolonged heating of the solution, sometimes under pressure. Under these conditions, industrially valuable crystalline silicates such as zeolites (→ Zeolites) or clays (e.g., kaolin) may be formed [136].

The addition of saturated sodium chloride or sodium nitrate solutions to silicate solutions precipitates alkali-containing silica gels which redissolve on dilution [121]. Saturated sodium sulfate and sodium carbonate solutions can be mixed with silicate solutions at room temperature without causing precipitation, as can strongly alkaline salts such as trisodium phosphate and sodium metaborate.

Most organic compounds are incompatible with soluble silicate solutions. Some polyhydric alcohols (e.g., glycerol) are compatible with sodium silicates and yield stable single-phase solutions. Other organics, such as polyol esters, produce a homogeneous system with silicate solutions but slowly react to give a solid mass [137]. Such systems have found use as setting systems (e.g., in the foundry industry and soil consolidation). Heating of sodium and potassium silicates in the absence of carbon dioxide initially produces very viscous solutions; as water loss continues, solid foams are formed that still contain significant amounts of water. Lithium silicates are stable at and around room temperature, but precipitate on heating to > ca. 60 °C. The effect is reversible upon cooling [138].

Production. Cold or warm lump glass (the latter to improve heat conservation) is usually dissolved at ≥ 5 bar and ca. 150 °C. Stationary systems may be used, but rotating vessels or circulation of the liquor accelerate dissolution rates. Direct steam heating is usually employed in large ($\geq 15\,m^3$) vessels. High glass : water ratios are used to give a satisfactory dissolution rate. Since the alkali silicates do not have a definite solubility in water, prolonged heating can lead to setting of the glass – liquid mix into an intractable elastic mass [122]. An excess of solid glass is heated with water until the required concentration is reached. The silicate solution, containing solid impurities (silicates of, for example, iron, titanium, alkaline earths) is removed from the residual excess glass. The solutions are then clarified by settling at elevated temperatures or by filtration. Some commercial silicate solutions are too viscous to be handled in this way, and are produced in a more dilute form, followed by evaporation of water under reduced pressure.

A variety of molar ratios and concentrations can be produced by appropriate mixing of a small number of silicate solutions produced directly from glass, either with each other or with the appropriate alkali hydroxide.

Sodium silicate solutions of molar ratio ≤ 2.5 can be prepared by direct dissolution of quartz sand in sodium hydroxide solution under pressure at $\leq$ ca. 150 °C. Even higher ratios can be obtained by this method if a more soluble form of silica is substituted for the quartz sand. Sodium silicates with R_W up to 3.3 may be obtained by this method using silica sources such as amorphous silica, diatomite, or cristobalite [123, 139].

Processes of this kind are likely to increase in importance because they require less energy than glass formation followed by dissolution.

As lithium silicate glasses are insoluble, lithium silicate solutions are prepared commercially by dissolution of amorphous silica in lithium hydroxide. Owing to the temperature instability of lithium silicate solutions, this process is carried out at or near room temperature.

3.5. Hydrated Water-Soluble Silicates

Hydrated water-soluble silicates are normally manufactured in the sodium form and are available as fine powders or as granules. In general they are prepared by evaporating silicate solutions to the point where solids are formed which are sufficiently stable to allow commercial handling but which retain adequate solubility. Typically this occurs at water contents of ca. 20 %. In principle a wide range of products with different ratios can be made, although in practice the ratio tends to be restricted to the range $R_W = 2.0$ – 3.3 where the products are amorphous. Unlike finely divided silicate glasses, these materials dissolve in water under normal conditions to give silicate solutions; the rate of dissolution is a function of ratio, water content, and particle size. Thus at low ratios ($R_W = 2.0$), materials in the size range 100 – 200 µm dissolve completely at room temperature in a few minutes, whereas a similar product with a higher ratio ($R_W = 3.3$) requires a higher temperature (≥ 50 °C) to achieve the same dissolution rate. These are, however, both considerably faster than the anhydrous glass analogues, for which dissolution takes many hours and may not go fully to completion.

In dissolving hydrated water soluble silicates, too large an excess of water should be avoided since rapid leaching of the alkali hydroxide can give a solution pH that is too low to attack the residual silicic acid, thus leaving it as an insoluble residue.

Examples of commercial materials are listed in Table 20. The manufacturing processes employed include spray or drum drying of silicate solutions followed by sieving to the required size. Granular materials are formed by mechanical compaction of the spray dried powders to give products which are more easily handled and are less dusty.

3.6. Crystalline Solids

Numerous crystalline alkali silicates have been reported both in anhydrous and hydrated forms [121]. The ratios vary typically from $R_W = 0.5$ to $R_W = 2.0$ and they are often referred to by the more traditional names:

Common name	R_W
orthosilicate ($SiO_2 \cdot 2Na_2O$)	0.5
sesquisilicate ($2SiO_2 \cdot 3Na_2O$)	0.67
metasilicate ($SiO_2 \cdot Na_2O$)	1.0
disilicate ($2SiO_2 \cdot Na_2O$)	2.0

Table 20. Hydrated, water soluble sodium silicates

Commercial name	Na_2O, wt %	SiO_2, wt %	Weight ratio	Molar ratio	Water, wt %	Bulk density, g/L
Pyramid P 40	26.7	53.3	2.00	2.06	20.0	400 – 500
Pyramid P 60	18.5	61.5	3.30	3.41	20.0	550 – 650
Pyramid P 10	28.0	56.0	2.00	2.06	16.0	80 – 120
Pyramid G 80	26.0	52.0	2.00	2.06	22.0	750 – 850
Pyramid G 90	26.0	52.0	2.00	2.06	22.0	800 – 950

In addition, several higher ratio silicates have been discovered and synthesized with ratios such as 4 : 1, 8 : 1, 9.4 : 1, 14 : 1, and 22 : 1 [140, 141]. Many of the latter are complex layered structures, often occurring naturally and having some cation exchange properties. The structured principles of all of these crystalline silicate species have been reviewed [142].

The only crystalline silicates which are presently of any commercial significance are the metasilicate family represented by the general formula $Na_2O \cdot SiO_2 \cdot nH_2O$. Products are available with $n = 0$, 5, 8 and 9, and within this range the anhydrous silicate ($n = 0$) and the pentahydrate ($n = 5$) are the most important. Metasilicate and its hydrates differ in structure. Whereas the anhydrous material contains infinite chains of general formula Na_2SiO_3, the hydrates, more properly represented by the formula $Na_2[SiO_2(OH)_2](n-1)H_2O$, contain the $[SiO_2(OH)_2]^{2-}$ ion as a discrete entity.

The metasilicates crystallize well and are readily soluble in water. Anhydrous sodium metasilicate melts congruently above 1018 °C, and above 70 °C it is the solid phase in equilibrium with aqueous solutions. Below this temperature, the hydrolyzed ion $[SiO_2(OH)_2]^{2-}$ is formed and the various hydrates can be crystallized. Although potassium metasilicates behave similarly, they are not commercial products.

Production. Anhydrous metasilicate is produced by two general methods:

1) It can be prepared in a furnace by direct fusion of sand and sodium carbonate at temperatures above the melting point of metasilicate (1088 °C), followed by solidification, grinding, and sieving. In some cases a solid-state reaction has been used above the melting point of sodium carbonate (850 °C) but below that of the metasilicate in rotary or tunnel kilns. The corrosive nature of metasilicate melts on furnace refractories makes this a less attractive route.
2) Alternatively, it can be obtained by drying solutions at the metasilicate composition in a fluidized bed [143] or a drum granulator [144]. In the latter case the hot liquor is sprayed on to the powder bed whose particles grow and dry uniformly in a current of hot air. At the end of the drum the beaded product is screened and the fines recycled to provide powder for further growth.

Metasilicate hydrates can be obtained by direct hydration of anhydrous metasilicate or by crystallization of a solution of metasilicate with the appropriate composition. In the case of metasilicate pentahydrate for example the heated solution of composition $Na_2O \cdot SiO_2 \cdot 5H_2O$ is kept above 72.2 °C (its melting point) and is crystallized by spraying on to a bed of particles cooled to below this temperature in a rotary drum granulator using a similar procedure to that described above for the anhydrous metasilicate.

Typical products and properties of metasilicates are shown in Table 21.

Of particular interest lately has been the preparation of synthetic layered silicate structure [145]. These materials of general composition $Na_2O \cdot 2\,SiO_2$ have ion-exchange properties.

3.7. Uses and Applications

The uses of alkali metal silicates fall into two broad categories:

1) As raw materials from which further important industrial products can be derived. This application utilizes the silicate anions as building blocks for the formation of a range of silica- containing materials and represents the single largest use of soluble silicates. These derived products include silica

Table 21. Typical properties of metasilicate products

Commercial name	Chemical formula	Water content, wt %	Bulk density, g/L	Average particle size, mm
Metso A 100	$Na_2O \cdot SiO_2$		1200	0.8
Metso 510	$Na_2O \cdot SiO_2 \cdot 5\,H_2O$	43	1000	0.8
Metso 520	$Na_2O \cdot SiO_2 \cdot 5\,H_2O$	43	1000	1.0
Metso 950	$Na_2O \cdot SiO_2 \cdot 9\,H_2O$	57	800	0.6

sols, silica gels, precipitated silicas, zeolites, aluminosilicates, magnesium silicates, synthetic clays, ceramics, and catalysts.

2) As functional additives in a wide range of applications exploiting the varied properties of the silicates.

These properties include: a source of buffered alkalinity; an inorganic polymeric system with adhesive, binder, and film-forming capabilities; nontoxic, nonflammable and environmentally benign; wide range of available compositions; capable of forming hybrid systems with organics (e.g., polymers) and other inorganics (phosphates, borates); complexation or precipitation of ions in solution; intumescent properties on heating; low cost.

Detergents represent the largest functional use of silicates. In broad terms use is made of the alkalinity and buffering capacity to aid in soil removal, assist in the suspension of soil particles, enhance the effectiveness of surfactants by sequestering calcium and magnesium ions, and inhibit corrosion of metal surfaces. In fabric washing powders [146] liquid silicates have traditionally been incorporated into the spray dried powders at levels of 5 – 15 %, whereby the silicate also provides crisp and easily handled detergent granules. The levels of incorporation of liquid silicates have been decreasing with the change to zeolite-based powders and more use is now being made of powdered soluble silicates added after spray drying. In industrial cleansing agents and dishwasher detergents the silicate product of choice has been metasilicate, either anhydrous or pentahydrate. There are now some concerns about the high alkalinity of such materials in domestic products and a move to granular soluble powders with higher ratio ($R_W \geq 2.0$) is likely to occur.

Foundries. Large quantities of liquid silicate (typically with $R_W = 2$) are used in the foundry industry to bind together sand molds and cores prior to pouring the molten metal. The silicate is set by reaction with CO_2 [147] blown through the silicate – sand mixture, or by incorporation of glycerol esters which hydrolyze and cause the setting reaction by release of organic acids [148].

Adhesives. Silicate liquors are used widely as adhesives. The largest consumer is the paper and board industry for such duties as spiral tube winding, corrugated boxboard, and fiber drums. Silicates are also used to bind insulating materials such as vermiculite in building panels, coal dust briquettes, roofing tiles, bricks and ceramics, refractory cements, and in the manufacture of welding rods. In the latter case, lithium silicate has proven to be particularly effective since it not only provides the necessary strength and degree of water resistance, it also reduces significantly the amount of Cr^{VI} evolved during the welding, thus providing safety benefits [149, 150].

Surface Coatings. Silicate liquors are used in a variety of surface coating applications. Examples include the sealing of porous surfaces such as concrete; as a vehicle for the preparation of paints for masonry and glass surfaces and for general fire proofing duties; and as a component in spray coating systems based on concrete and glass fiber. Silicates are also used to coat TiO_2 pigment particles to improve stability.

Paper Deinking and Bleaching. Sodium silicate liquors are used in the paper industry to promote deinking of recycled newsprint and also to act as a promoter to achieve enhanced bleaching with hydrogen peroxide. Both of these are environmentally driven applications, and demand is expected to grow as pressure increases to recycle more paper and to switch from chlorine to peroxide- containing bleaches.

Water Treatment. Silicates are added to water, including potable water, in concentrations

of a few ppm to prevent discoloration due to dissolved iron. The precise mechanism is not fully understood, but it appears that the silicate forms a "soluble" iron – hydroxide – silicate complex which prevents the formation of visible iron flocs. An additional benefit of such water treatment with silicate is the corrosion protection afforded to metal pipes, presumably by similar complex formation at the metal surface. Other water treatment uses have included a coagulation aid in alum flocculation processes and for boiler water treatment.

Civil Engineering. Silicates are used to stabilize soils in many civil engineering projects involving drilling, tunneling, and mining. Silicate solutions mixed with appropriate setting agents are pumped into the ground where they harden the soil [151]. An interesting application of this technology is the Sanipor process for repairing sewers without the need to dig up city roads and streets [152–154]. Other similar uses include sealing around landfill sites, waste fixation, and coastline stabilization.

Enhanced Oil Recovery. Use of silicates with considerable growth potential is in enhanced or tertiary oil recovery, particularly in offshore locations. Flooding the oil field with silicate solutions promotes the formation in situ of soaps and surfactants which improve the oil flow from the porous rock [155, 156].

3.8. Economic Aspects

Estimated 1990 world silicate consumption (expressed as dry glass) is ca. 4×10^6 t (including captive use). The approximate geographic split is United States, Japan and Western Europe 20 % each with the remaining 40 % for the rest of the world. The latter figure is speculative since it does not include Eastern Europe and China. The sales value of the noncaptive volume is ca. $\$1.5\times10^9$. Consumption is estimated at 65 – 75 % of installed capacity.

The volume of silicate supplied to the merchant market, expressed as 100 % solids, is estimated to be:

United States	470 000 t
Western Europe	500 000 t
Japan	500 000 t

Table 22 shows the breakdown of the total volume by application for Western Europe and the United States.

Table 22. Silicate usage by industry application (in percent)

Application	Western Europe	United States
Detergents	28.1	32.6
Paper	7.3	7.5
TiO_2	4.6	4.6
Water treatment	2.9	3.5
Civil engineering	7.7	
Miscellaneous	6.4	5.8
Total	57	54
Derivatives (silica, zeolites etc)	43	46
Total	100	100

3.9. Storage, Safety, Labelling and Transportation

The CAS und EINECS numbers are shown in Table 23 for various soluble silicates.

A comprehensive review of the health and safety aspects of silicates has been published [157, 158]. The primary hazard of all soluble silicates is their alkalinity. Contact effects range from irritation to corrosion. Ingested or inhaled silicates are rapidly eliminated in the urine. Quoted LD_{50} (oral, rat) values are 1280 mg/kg for sodium metasilicate, 1300 mg/kg for sodium silicates with $R_W = 2.0$, and 1600 mg/kg for $R_W = 3.0$ according to the Registry of Toxic Effects of Chemical Substances 1981 – 1982. There are no exposure limits quoted for sodium or potassium silicates by any regulatory body. A limit of 2 mg/m^3 is given for caustic soda and caustic potash by both ACGIH and the HSE (under the EH40/92 exposure regulations) and exposure to silicate should therefore be limited, according to its composition, to remain in line with the caustic soda and potash figures. For lithium silicates a similar situation prevails, but the exposure limit for lithium hydroxide is 1 mg/m^3.

Alkali silicates are not flammable or explosive. Due to their alkalinity, solutions attack aluminum, tin, and zinc, with evolution of hydrogen, at concentrations above ca. 10 %. Powdered silicates tend to be hygroscopic and packaging must therefore provide adequate protection against water vapor ingress to avoid caking. Avoidance of prolonged contact with CO_2

Table 23. CAS and EINECS numbers for various soluble silicates

Product	Formula	CAS registry no.	EINECS no.
Sodium silicate solutions, glasses, or solids	$Na_2O(SiO_2)_x$ $x > 1.6$	[*1344-09-8*]	2 156 874
Sodium metasilicate and hydrate	$Na_2O \cdot SiO_2(H_2O)_y$ $y = 0, 5, 9$	[*6834-92-0*]	2 299 129
Sodium orthosilicate	$2Na_2O \cdot SiO_2$	[*13472-30-5*]	2 367 413
Sodium sesquisilicate	$3Na_2O \cdot 2SiO_2$	[*15593-82-5*]	2 396 711
Potassium silicates	$K_2O(SiO_2)_x$ $x > 1.6$	[*1312-76-1*]	2 151 991
Lithium silicate solutions	$Li_2O(SiO_2)_x$ $6 \leq x \leq 12$	[*12627-14-4*]	2 357 300

is also necessary since both solids and solutions will readily absorb this from the air to form alkali metal carbonates.

Under the rules of the EEC Dangerous Substances Directive 67/548/EEC as amended by 92/32/EEC all silicates with $R_W \geq 1.6$ are classified as irritant. However, the labeling classification for sodium silicates is under review in Europe and a new set of safety phrases will be agreed taking into account both R_W and concentration.

In the environment, commercial silicates rapidly depolymerize on dilution to give molecular species indistinguishable from natural dissolved silica in ground waters. The pH of most silicate solutions is however above the acceptable limit for direct discharge to rivers and sewers, and dilution or neutralization must be carried out first. For disposal to landfill, the classification of silicates varies according to composition and also by countries. In general the more alkaline the products the more likely it is to be classified as hazardous or special waste although concentration is also important. Thus in the United Kingdom metasilicates above 0.1 % and all silicate solutions above 10 % qualify as special waste [159].

3.10. Analysis

The alkali-metal content of soluble silicates is determined by titration in dilute solution with hydrochloric or sulfuric acid using methyl orange as indicator. The silica is determined gravimetrically. Alkali metals are removed as the chlorides by fuming the diluted silicate solution several times with hydrochloric acid in a flat porcelain dish. The insoluble silica is then filtered, washed, calcined, and then weighed. If very great accuracy is required, the silica is volatilized by fuming with hydrofluoric and sulfuric acids. The sesquioxides remaining after this are accounted for in the calcination.

Potassium silicate glasses are dissolved and fumed with hydrochloric acid to give silica-free filtrates whose sodium content is determined by flame photometry. The potassium content of sodium silicate glasses is determined analogously.

The silica content of aqueous silicate solutions can be determined more conveniently by titration. The solution is neutralized using methyl red as indicator, an excess of pure sodium fluoride is then added, and the alkali that is liberated according to the equation

$$SiO_2 + 6\,F^- + 2\,H_2O \longrightarrow SiF_6^{2-} + 4\,OH^-$$

is backtitrated with hydrochloric acid.

Chloride is titrated by the argentometric method in a dilute aqueous solution of the silicate. Sulfate is determined by precipitation as barium sulfate from the filtrate from which the silica has been removed.

Other possible impurities (CO_2, Al_2O_3, Fe_2O_3, TiO_2, CaO, MgO) are determined by the methods used for analyzing ordinary glass. Spectrophotometry is recommended, particularly for iron and titanium.

Alkali silicates that are normally insoluble in water are dissolved by pressure dissolution and investigated as for soluble silicates. Remaining insoluble matter is weighed and may be analyzed as for water-insoluble silicates.

Since 1972, the following ISO specifications for alkali silicate analysis were published, 1686: general, 1687: density of silicate solutions, 1688: density of the dry substance, 1689:

determination of ratio, 1690: gravimetric determination of SiO_2 content, 1691: gas volumetric determination of CO_2 content, 1692: titration of alkalinity, 2122: preparation of solutions of solid alkali silicates and determination of insoluble components, 2123: determination of dynamic viscosity of silicate solutions, 2124: titrimetric determination of SiO_2 content, 3200: gravimetric determination of SO_4^{-2} content of alkali silicates, 3201: photometric determination of iron content of alkali silicates.

1. Introduction

Silicon, Si, is a gray, metallically lustrous element with atomic number 14 and atomic mass 28.086. It is a member of group 14 of the periodic table, situated between carbon and germanium, and has three natural isotopes: ^{28}Si (92.2 %), ^{29}Si (4.7 %), and ^{30}Si (3.1 %). Corresponding to its position in the periodic table, silicon has four valence electrons, two of them in the 3 *s* and two in the 3 *p* levels. It crystallizes in the diamond structure like diamond, germanium, and α-tin. Silicon is a nonmetallic, semiconducting element with a resistivity of ca. 400 kΩ · cm at room temperature in its purest state. Its electrical resistivity decreases with increasing temperature and increasing concentration of electrically active elements such as B, Al, Ga, In, Tl, P, As, and Sb. By doping silicon with boron, for example, its room-temperature resistivity can be reduced by nine orders of magnitude to ca. 0.4 mΩ · cm. Except for very thin foil, silicon is impermeable to visible light, but it is highly permeable to infrared light. The IR permeability decreases with decreasing electrical resistivity.

After oxygen (50.5 %), silicon is the second most abundant element (27.5 %) in the lithospere. It does not occur in elemental form, but only in oxides and silicates.

Modern electronics is almost exclusively (> 95 %) based on silicon devices, both in low-power and in high-power electronics, a situation that will continue for at least the next few decades. Because of the eminent and ever increasing importance of electronics in technology and everyday life, silicon is one of the most important technical materials, although the quantity required for this application is relatively small (ca. 10 000 t of electronic-grade silicon in 1992). This small quantity results from the very small dimensions of electronic devices (e.g., 0.5×4×4 mm).

Of secondary importance are the uses of silicon for metallurgy and chemistry (silicon compounds), although they consume the major portion of the silicon produced.

2. History

The name silicon derives from the Latin word *silex* (= flint). Even in ancient times, silicon compounds were used for the production of glass. The first attempts to obtain elemental silicon from silica were made in the 1700s, but only in 1810 did Berzelius succeed in isolating silicon from ferrosilicon by reduction with carbon and iron at the melting point of iron. In 1823, he obtained iron-free silicon by reducing SiF_4 with potassium metal.

In 1854, Sainte-Claire Deville obtained coarse-grained silicon by fusion electrolysis

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_721

of silicon-containing $NaAlCl_4$. Further important developments were achieved by WÖHLER (1855), WINKLER (1864), SCHEID (1899), and KÜHNE (1902). Commercial production of ferrosilicon (iron-rich silicon), which had proved to be an excellent deoxidant in steel production, began in the early 1900s as an offshoot of calcium carbide production. Ferrosilicon is produced in the same type of furnace as calcium carbide and is a byproduct of calcium carbide production.

3. Physical and Chemical Properties

Physical Properties. Some physical properties of silicon are as follows (values without references are taken from [1]):

Atomic number	14
A_r	28.086
Lattice constant	0.5431 nm (= edge length of the cubic unit cell)
Interatomic distance in ⟨111⟩ direction	0.2352 nm
Atomic density	5.00×10^{22} atoms/cm^3
Density at 300 K	2.329 g/cm^3
Density at melting point	
Solid	2.30 g/cm^3
Liquid	2.51 g/cm^3
Volume increase at transition from liquid to solid	+9.1 %
Specific heat (300 K)	0.713 J g^{-1} K^{-1}
Thermal expansion (300 K)	2.6×10^{-6}/K
Thermal conductivity (300 K)	1.5 W cm^{-1} K^{-1}
mp	1687 K
bp	3504 K [2]
Critical temperature	5193 K
Critical pressure	145 MPa
Latent heat of fusion	50.66 kJ/mol
Heat of evaporation	385 kJ/mol
Combustion heat, H_0 (Si/SiO_2)	850 kJ/mol
Bulk modulus (300 K)	97.84 Pa
Vickers hardness	10.2 GPa
Mohs hardness	7
Surface tension at melting point	885 mJ/m^2
Band gap (300 K)	1.126 eV
Electron mobility	1440 cm^2 V^{-1} s^{-1}
Hole mobility	484 cm^2 V^{-1} s^{-1}

Chemical Properties. As an element of group 14 of the periodic table, silicon represents the transition from the base metals of groups 1, 2, and 13 to the metalloids and nonmetals of groups 15–17. With nonmetals of higher electronegativity, silicon forms predominantly nonpolar compounds such as Si_3N_4 or SiC, as well as more polar compounds such as SiO_2 and SiF_4 with oxidation state 4^+. If Si–Si bonds are present, the mean oxidation state is lower (e.g., 3^+ in Si_2I_6).

Figure 1. Free energy of selected reactions for production of silicon from SiO_2 and silicon tetrahalides [5]

Silicon binds oxygen dissolved or present as compounds in metal melts to give SiO_2 or SiO, and it may partially evaporate in the form of the volatile SiO. With metals, silicon forms alloys, intermetallic compounds, or silicides.

Bulk silicon is very resistant to acid, including HF or HNO_3, but not to a mixture of HF and HNO_3. In this mixture, HF first etches away the SiO_2 layer from the silicon surface, then HNO_3 oxidizes silicon again, the new SiO_2 layer is removed by HF, and so on. Silicon reacts violently with even dilute alkaline solutions to generate hydrogen. Heating in an oxygen-containing atmosphere forms an SiO_2 layer that inhibits further oxidation. Above 520 K, silicon reacts with HCl to form $SiHCl_3$ and $SiCl_4$ (→ Silicon Compounds, Inorganic), and with CH_3Cl in the presence of copper to give alkylchlorosilanes

(→ Silicon Compounds, Organic). At ca. 620 K, silicon and HBr give $SiBr_4$ and $SiHBr_3$. At room temperature, silicon and fluorine produce SiF_4.

4. Production

4.1. Metallurgical Silicon

Since the turn of the century, silicon has been produced almost exclusively by carbothermal reduction of silicon dioxide:

$$SiO_2 + 2\,C \longrightarrow Si + 2\,CO \quad \Delta H_{298} = 695\,kJ$$

Another way to produce silicon from SiO_2 is aluminothermal reduction:

$$3\,SiO_2 + 4\,Al \longrightarrow 3\,Si + 2\,Al_2O_3 \quad \Delta H_{298} = -619\,kJ$$

Figure 1 shows the free energy of reaction ΔG_0 of the two reactions for the range 900 to 2100 K. Whereas carbothermic reaction of SiO_2 is unattractive below 2000 K, reduction with aluminum is strongly exothermic over the entire temperature range. In carbothermic reaction, the side reactions

$$SiO_2 + C \longrightarrow SiO + CO$$

and

$$SiO_2 + 3\,C \longrightarrow SiC + 2\,CO$$

must be avoided.

For the carbothermal production of silicon and ferrosilicon, electric-arc furnaces (Fig. 2) are used. For silicon production, graphite electrodes are used, whereas for the production of ferrosilicon, Söderberg electrodes (steel tubes filled with a mixture of coal powder, tar, and pitch) are employed. The carbothermal process yields silicon with a purity of ca. 98 % (metallurgical-grade silicon, MG-Si), for which a typical analysis is 0.5 % Fe; 0.4 % Al; 100 – 400 ppm each of Ca, Cr, Mg, Mn, Ni, Ti, and V; and 20 – 40 ppm each of B, Cu, P, and Zr. The usual starting materials are chunks of quartzite, coke, as well as charcoal and wood chips for good ventilation of the charge. To produce 1 t of silicon, 2.9 – 3.1 t of quartz or quartzite, 1.2 – 1.4 t of coke (gas coke and petroleum coke), and 1.7 – 2.5 t of charcoal and wood are required. The consumption of electrode graphite is 120 – 140 kg/t Si, which must be added to the amount of reducing agent, and of electrical energy is 12.5 – 14 MW · h/t Si. The purity of the silicon produced depends primarily on the purity of these materials and secondarily on the purity of the graphite electrodes and the furnace lining.

Figure 2. Arc furnace for silicon production [5]
a) Input of quartz and carbon; b) Electrode holder; c) Electric contact; d) Carbon electrode; e) Tapping electrode

The purity of silicon can be increased by using purer starting materials, by improving the furnace construction, and by optimizing the production process. Dow Corning [3], [4] has introduced an improved arc furnace, the so-called direct arc reactor (DAR), which yields purer silicon. With adequately pure starting and furnace materials and with optimized operation, the DAR process gives silicon with a purity of 99.99 %. Residual impurities are Al, Fe (50 – 100 ppm each), and other metals, as well as B and P (< 10 ppm each).

Another method of producing silicon starts with silicon tetrafluoride, which is a byproduct of the production of superphosphate fertilizer from phosphate rock. The ore contains CaF_2, which is converted to HF when treated with H_2SO_4; HF then reacts with SiO_2 to form SiF_4, with an estimated 75 000 t/a being recovered in the United States as fluosilicic acid, H_2SiF_6. Sodium fluoride is added to the H_2SiF_6 to form sodium fluosilicate:

$$H_2SiF_6(aq.) + 2\,NaF\,(s) \longrightarrow Na_2SiF_6(s) + 2\,HF\,(aq.)$$

After filtration and drying, Na_2SiF_6 is decomposed at 920 K:

$$Na_2SiF_6(s) \xrightarrow{\Delta} SiF_4(g) + 2\,NaF(s)$$

Then, SiF_4 is purified by passing it over iron at 1070 K to remove air and SO_2, and by subsequent fractional distillation. Silicon tetrafluoride can be reduced readily to silicon by reaction with sodium:

$$SiF_4(g) + 4\,Na(l) \longrightarrow Si\,(powder) + 4\,NaF(s)$$

The exothermic character of this reaction provides sufficient heat to maintain the process at 770 K. To separate silicon from NaF, the Si –NaF mixture is melted to form two immiscible phases for which liquid – liquid extraction (migration of impurities from silicon to NaF) provides additional purification. This reduction process is known as the SRI (Stanford Research Institute International) process [6], [7]. Because the reduction reaction yields four times as much NaF as silicon, low- cost silicon is attainable only if the byproduct can be sold.

An alternative way to transform H_2SiF_6(aq.) into elemental silicon is used by Ethyl Corporation [8]:

$$H_2SiF_6(aq.) \xrightarrow{\Delta} SiF_4 + 2\,HF$$
$$SiF_4(g) + NaAlH_4(s) \longrightarrow SiH_4(g) + NaAlF_4(s) \qquad (1)$$

Also, $KAlH_4$ or a mixture of $NaAlH_4$ and $KAlH_4$ can be used. $NaAlF_4$ is used in aluminum production, and SiH_4 is decomposed at ca. 1000 K to generate elemental silicon:

$$SiH_4(g) \longrightarrow Si(s) + 2\,H_2(g) \qquad (2)$$

About 150 other reactions yield elemental silicon, but most of them are not used in industrial production.

Ferrosilicon production, ca. 2×10^6 t in 1992, constitutes the major part of industrial silicon production. Ferrosilicon is used in steelmaking, mainly as a deoxidizer, but also as an alloying element (e.g., for the production of transformer sheet metal).

World production of metallurgical-grade silicon in 1991 was ca. 650 000 t, with a market price of ca. $ 1.5/kg. About 60 % was used as an alloying element for nonferrous metals, particularly aluminum alloys; ca. 37 % for the production of silicon compounds; and ca. 3 % for electronic applications (electronic devices, solar cells, sensors, micromechanics). The main producer countries for MG silicon are Norway, the United States, France, Canada, the Republic of South Africa, the CIS, Italy, Spain, and Yugoslavia.

4.2. Semiconductor Silicon

4.2.1. Purification

For applications in electronics, photovoltaics, sensors, and micromechanics, metallurgical-grade silicon must be refined to a much higher purity. Purity requirements for the fabrication of high-efficiency solar cells, for example, are nearly as high as those for advanced semiconductor devices.

At present, the main refining steps are the adsorption and distillation of a silicon compound. For this purpose, silicon is first converted into a compound such as $SiHCl_3$, $SiCl_4$, SiH_2Cl_2, or SiH_4. After purification, the silicon compound is transformed back into elemental, high-purity silicon by chemical vapor deposition (CVD). Alternative refining methods [5] have not been used in industrial production up to the present.

The starting material for the production of semiconductor-grade silicon (SG-Si) is about 90 % carbothermal silicon and about 10 % silicon produced by the Ethyl process [8].

Carbothermal silicon, milled to a sand or powder, is fed into a fluidized-bed reactor where it is fluidized by a stream of hydrogen chloride flowing through small orifices in the bottom of the reactor (see Fig. 3). The reactor is held at ca. 650 °C and the exothermic reaction yields predominantly trichlorosilane and hydrogen,

$$Si + 3\,HCl \rightleftharpoons SiHCl_3 + H_2 \qquad (3)$$

as well as silicon tetrachloride:

$$Si + 4\,HCl \rightleftharpoons SiCl_4 + 2\,H_2$$

In addition to $SiHCl_3$ and $SiCl_4$, other chlorosilanes and compounds of the impurities with chlorine or hydrogen are formed. After removal of silicon powder, impure trichlorosilane is condensed and stored in an intermediate tank, and

Figure 3. Flow chart of the preparation and refining of trichlorosilane
a) Fluidized-bed reactor; b) Dust filter; c) Condenser; d) Tanks, e) Distillation of low-boiling impurities; f) Distillation of high boilers; g) Tanks; h) Storage tanks

subsequently purified by adsorption and distillation (see Fig. 3). Because of its favorable boiling point of 305 K, trichlorosilane can be purified effectively by fractional distillation. To improve the removal of boron and phosphorus, the two most important electrically active elements in silicon, boron(III) and phosphorus(III) chloride are transformed into less volatile compounds before distillation by use of complexing agents. In this way, the production of trichlorosilane with boron and phosphorus contents of < 1 ppba (parts per billion atomic) is possible.

From the point of view of chemical process engineering, trichlorosilane is easiest to handle and most economical. About 90 % of the electronic-grade silicon is purified by distillation of trichlorosilane, and the rest by distillation of silane, SiH_4. The distillation of SiH_4 is applied only after the Ethyl process (Eq. 1). Silane is much more dangerous to handle than trichlorosilane.

4.2.2. Chemical Vapor Deposition

All semiconductor-grade silicon is produced by converting silicon compounds to elemental silicon by chemical vapor deposition (CVD). For ca. 75 % of worldwide CVD production, trichlorosilane is used as the silicon compound (e.g., by Wacker, Hemlock, Tokuyama Soda, Kyundo, OTC, MEMC); for ca. 25 %, silane (ASiMI, Ethyl), partly produced from trichlorosilane, is used.

The method of converting trichlorosilane into high-purity silicon was first developed by Siemens & Halske in 1952 and patented in 1956 [9]. It employs the reverse of Equation (3), which is strongly endothermic and therefore requires a high reaction temperature (ca. 1400 K). This reaction also yields much tetrachlorosilane as byproduct:

$$4\,SiHCl_3 + 2\,H_2 \rightleftharpoons 3\,Si + SiCl_4 + 8\,HCl \quad \Delta H = 964\,kJ$$

The byproduct $SiCl_4$ is partly converted back to trichlorosilane in the reactions

$$SiCl_4 + H_2 \rightleftharpoons SiHCl_3 + HCl$$

$$Si + 3\,SiCl_4 + 2\,H_2 \rightleftharpoons 4\,SiHCl_3$$

The remaining $SiCl_4$ is used for the production of highly dispersed SiO_2 (e.g., HDK from

Wacker) and synthetic silica glass and glass fibers, and for silicon epitaxy in the production of electronic devices.

To avoid the deposition of silicon on unwanted and contaminating surfaces, the CVD arrangement shown schematically in Figure 4 is used. In a bell-jar reactor, three silicon slim-rods (ca. 8 mm in diameter, semiconductor grade, float zone pulled in a specially designed apparatus) are mounted in the form of an inverted U and are resistance heated electrically to ca. 1400 K, while the bell jar is kept cold. In this way, the heat required for the reaction is available only on the surface of the silicon rods; silicon forms there exclusively and adheres to the rods. Elemental silicon not adhering to the rods is transformed back to a gaseous silicon compound at lower temperature (e.g., see Eq. 3) in the reactive atmosphere around the rods.

Figure 4. Chemical vapor deposition of silicon
a) Electrical current; b) Starting silicon slim-rod; c) CVD polycrystalline silicon rod (1400 K); d) Reactor (silica, metal); e) Saturator

In the CVD process, the concentration of impurities is again reduced [10], in the case of boron and phosphorus by a factor of up to 1000. The trichlorosilane CVD process yields silicon with < 0.02 ppba boron and < 0.01 pbba phosphorus, so that further refining of the CVD silicon by zone melting for electronic applications is no longer necessary in most cases, in contrast to the situation at the beginning of semiconductor-grade silicon production.

Silicon single crystals can also be grown by CVD if monocrystalline slim-rods are used. However, this process is very expensive because of the very low growth rate that must be used for single- crystal growth, and it yields low-quality single crystals. Therefore, the CVD silicon produced today is a fine-grained, polycrystalline material used as starting material for the melt growth of single crystals.

In the CVD process, much energy is lost by thermal radiation from the silicon rods. The radiant energy is absorbed largely by the cold reactor walls. Energy is therefore the primary cost factor in this process; thus endeavors are made to maximize the deposition rate. Theoretically, the highest growth rate is ca. 2 mm/h; however, growth rates used in industry are lower – ca. 1 mm/h or less.

The upper limit for the deposition rate is determined by the required silicon quality, especially in the production of silicon rods for float-zone crystal growth (see page 11), which requires long cylindrical silicon feed rods, free of cracks and voids, and with a smooth surface, as starting material. Too rapid a growth rate results in dendritic growth, which gives a rough surface, voids, and cracks in the material. Such a feed rod would either crack or emit silicon particles on melting during float-zone growth.

Whereas the diameter of the feed rods for float-zone growth is determined by the requirements of the crystal growth process (the diameter of the feed rods should be a little larger than that of the crystals to be grown), CVD silicon rods for the growth of crucible-pulled crystals may be of any diameter. Therefore, CVD rods for crucible pulling are always grown to the largest possible diameter for economic reasons: the CVD yield (kg/W · h) and the CVD output (kg/h) increase linearly with the radius of the rod at a constant deposition rate. However, the maximum diameter of CVD rods is ca. 25 cm, since at larger diameters, the center of the rod begins to melt and the rod system breaks down, causing damage to the reactor and contamination of the silicon.

Therefore, the deposition process is stopped at a rod diameter known to exhibit no melting.

At present, CVD processes run automatically. Process parameters such as current, temperature, pressure, gas flow, and concentration are measured continuously and are used by a computer to calculate new control parameters. Rod lengths > 2 m and rod numbers of 8 – 16 per reactor are usual today.

A different method of producing CVD silicon is used by ASiMI (formerly UCC), which transforms $SiHCl_3$ into SiH_4 and performs the CVD process with SiH_4 at ca. 1000 K. The CVD reactor and arrangement are similar to those used for deposition with $SiHCl_3$ (deposition on silicon rods, see Fig. 4). The transformation of trichlorosilane into silane occurs according to the following reactions:

$$6\,SiHCl_3 \overset{cat.}{\rightleftharpoons} 3\,SiCl_4 + 3\,SiH_2Cl_2$$

$$4\,SiH_2Cl_2 \rightleftharpoons 2\,SiHCl_3 + 2\,SiH_3Cl$$

$$2\,SiH_3Cl \rightleftharpoons SiH_4 + SiH_2Cl_2$$

$$4\,SiHCl_3 \rightleftharpoons 3\,SiCl_4 + SiH_4$$

The CVD reaction is the decomposition of silane:

$$SiH_4 \longrightarrow Si + 2\,H_2 \qquad (4)$$

A very different way of transforming silane into elemental silicon is used by Ethyl, United States [11], and KRICT, Korea [12], based on a Texas Instruments patent [13].

A mixture of ca. 20 mol % silane and 80 mol % hydrogen is fed through a gas-dispersing frit into the bottom of a reactor; a fine silicon powder is let in through an opening at the top of the reactor and fluidized by the upflowing gas. The silicon powder is heated to ca. 1000 K, and silane decomposes according to Equation (4) into silicon and hydrogen on the hot silicon particles. The silicon particles grow, and the larger ones fall to the bottom of the reactor where they are removed through an opening.

In the Ethyl process, the silicon particles are heated from outside the reactor by resistance heating (see Fig. 5). This leads to problems with unwanted deposition of silicon on the hot walls of the reactor.

Figure 5. Chemical vapor deposition of granular silicon
a) Silicon powder; b) Powder-feeding device; c) Exhaust; d) Fluidized-bed reactor; e) Heating (resistance or microwave); f) Removal of coarse silicon granules; g) Container for silicon granules; h) Gas injection

This problem is overcome in the newer KRICT process. Silicon particles are heated with microwaves, and the reactor wall remains cold if it is made from an appropriate material (e.g., silica).

Granular CVD silicon has major advantages over rod-shaped CVD silicon for feeding, particularly for continuous feeding of the melt with silicon during crystal growth, because the round silicon granules flow much better than the sharp-cornered grains of broken CVD silicon rods. Moreover, breaking the rods contaminates the silicon severely.

In 1992, the world production of electronic-grade CVD silicon was ca. 10 000 t with a market value of ca. $\$\,500 \times 10^6$ (\$ 50/kg).

4.2.3. Single-Crystal Growth

More than 95 % of all electronic devices are made from single-crystal silicon. In addition, single-crystal silicon is used at present for ca.

40 % of all photovoltaic solar cells and for all micromechanical devices. Two crystal growth methods are used in industry for the production of silicon single crystals: the Czochralski (CZ) method, which yields about 85 % of all silicon crystals, and the float-zone (FZ) method, which yields 15 % of the silicon crystals. The CZ crystals are used mainly for manufacturing highly integrated low-power devices, typically for microprocessors, RAMs, DRAMs, ASICs, etc., whereas the FZ crystals are used mainly for making discrete or low-integrated high-power devices such as diodes, transistors, and thyristors.

Czochralski Crystal Growth. The Czochralski method [14] uses a crucible for crystal pulling and is therefore also known as crucible pulling (see Fig. 6; for more detailed information, see [15–17]). A silicon melt is held in a crucible, and a single- crystal seed of the proper orientation is dipped into the melt and slowly withdrawn vertically. With suitable pulling speed and crystal and crucible rotation rate, a single crystal of the desired shape can be grown.

To eliminate dislocations, which always occur on immersing the seed crystal, a thin crystal neck (ca. 3 – 5 mm in diameter and several centimeters long) must be grown with a growth rate of several millimeters per minute. Because of the small diameter, the thermal strains in the neck are too low and the growth rate is too high for propagation of dislocations downward into the growing crystal, and the crystal neck becomes dislocation free after a few centimeters. The same procedure is used in float-zone pulling.

The dislocation-free state is stable, and large diameters can be grown despite the high cooling strains in large crystals. After neck growth, the diameter is increased to the nominal crystal diameter and then kept constant by adjusting the pulling rate and the heating power. Dislocation-free crystal growth can be completed by reducing the crystal diameter to nearly zero at the end of the crystal.

Table 1. Equilibrium distribution coefficients k_0 and typical concentrations of impurities in CVD-Si and CZ-Si

Usually, a small residual melt remains in the crucible, the amount of which depends on quality demands and economic factors. Owing to the segregation effect, the majority of the impurities remain in the melt since most of them have very low segregation coefficients (see Table 1).

The silicon melt reacts with all materials to some extent. Only silica can be used as crucible material, because the product of its reaction with the silicon melt, silicon monoxide (SiO), evaporates readily from the melt. Thus supersaturation of the melt with oxygen or SiO is prevented. Supersaturation of oxygen in the melt would cause supersaturation of oxygen in the crystal, oxygen precipitation, and the formation of dislocations in the crystal near the freezing interface. The growth of a dislocation-free crystal would be impossible. All other crucible materials either contaminate the silicon crystal with impurities (e.g., Al_2O_3 or ZrO_2) or cause dislocated crystal growth by supersaturation (e.g., SiC and Si_3N_4).

Both to promote the evaporation and removal of SiO and to prevent the backflow of CO and other reaction and evaporation products, the furnace is purged with a strong argon stream and the pressure is kept low (generally 10 – 100 mbar). Table 2 gives an overview of the basic data for industrial silicon crystal growth.

About 1.5 g of silica is dissolved per 1000 g of CZ-Si crystal during growth, but $< 1\,\%$ of the oxygen in the dissolved silica is found in the crystal. This indicates that the evaporation rate of SiO is very high and the oxygen content of the melt is exchanged every 10 min. Accordingly, oxygen transport from the crucible to the crystal and thus the oxygen content of the crystal can be manipulated over a wide range by influencing convective flows in the melt and the evaporation of SiO at the melt surface.

Impurities in the dissolved silica are absorbed by the silicon melt. However, only a small portion of impurities are incorporated into the crystal owing to the segregation effect, which is very strong for most elements (see Table 1). For example, from 100 000 iron atoms in the melt, only one atom is incorporated into the crystal. As a result of this strong segregation, the impurity content of the CZ-Si crystal is lower than that of the starting material for most elements.

Figure 6 shows the basic arrangement of a CZ-Si crystal puller, and Figure 7 shows a photograph of such a crystal puller during removal of a grown crystal. The best and most economical heating method is resistance heating with a graphite heating element. The soft silica crucible must be supported by a graphite crucible. The diameter of the crystal is monitored by an optical system (e.g., a CCD camera) and, in most cases, the melt and furnace temperatures are measured by pyrometers. The crystal and the crucible can be moved and rotated very precisely. A valve between the front-opening chamber and the furnace allows the removal of the crystal while the furnace is hot and refilling of the hot crucible(containing residual melt) with polycrystalline silicon and dopant. The growth control of modern crystal pullers allows completely automatic crystal growth. However, with monitoring and correction by an operator, the yield of the crystal grower can be improved. In 1992, the standard diameters of commercial CZ-Si crystals ranged from 50 to 200 mm, averaging 150 mm, and CZ-Si crystals 300 mm in diameter are being developed.

Figure 7. Removal of a large CZ silicon crystal (diameter 204 mm, weight 50 kg) that is still hanging from the seed crystal

Float-Zone Crystal Growth. Figure 8 shows the basic arrangement for large diameter float-zone silicon crystal growth in a modern FZ puller. The FZ-Si method differs from the CZ-Si method mainly in the absence of a crucible and in the small melt volume. The absence of

∗ The maximum concentration for dislocation-free growth is generally lower than the maximum solubility in silicon (at ca. 1550 K) due to the effect of retrograde solubility for most of the elements (for most elements, solubility increases up to ca. 1550 K, then decreases continually up to the melting point of 1687 K). The maximum growth and rotation rates decrease with increasing crystal and crucible diameters.

∗∗ Concentration in number of impurity atoms per cm^3 of silicon; 1 cm^3 Si contains 5.00×10^{22} atoms.

a crucible results in a very low oxygen content and in lower concentrations of impurities compared to CZ-Si crystals. The small melt volume leads to an axially constant boron or phosphorus concentration in contrast to CZ-Si (see Fig. 9). Boron and phosphorus are the only dopants used in industrial FZ-Si production.

The starting material for the growth of an FZ-Si single crystal is a polycrystalline silicon feed rod clamped to a movable shaft. The feed rod can be unmelted CVD silicon or FZ-premelted silicon (CVD rods that have been float zone grown to give cylindrical, bubble- and crack-free polycrystalline rods). An induction coil melts the feed rod at the bottom, generating a large melt drop. A slim seed crystal is moved through the narrow opening in the center of the induction coil and brought into contact with the melt drop. Upon movement of the seed crystal downward the melt crystallizes on it and the seed crystal grows.

As in CZ-Si pulling, a dislocation-free state must be generated by growing a neck prior to growth of the large-diameter crystal. After the crystal diameter is increased, melt and crystal are heated from above by the induction coil, not laterally as in the case of small crystal diameters. The melt lies on top of the crystal and is held together mainly by its surface tension and partly by electromagnetic forces. It is connected to the feed rod by a slim melt neck through which the melt flows from the feed rod to the crystal. At the end of the crystal growth process, the FZ melt freezes on top of the crystal and generates dislocations. The dislocations multiply and propagate into the crystal over a distance of about one-half the crystal diameter.

The height of the melt at the edge of the crystal is only several millimeters and does not depend on crystal diameter. Therefore, the growth of large crystal diameters is not limited by heating problems, as was assumed earlier. The FZ-Si crystals can be grown to similar dimensions as CZ-Si crystals. The main problem in the growth of large-diameter FZ-Si crystals is the high thermal stress. The temperature gradients are larger

in growing FZ-Si crystals than in growing CZ-Si crystals of the same diameter because FZ-Si rods cool faster. The CZ-Si crystals are reheated by thermal radiation from the melt, the crucible, and the heater. For the growth of large diameters, cooling of the FZ-Si crystals must be reduced.

Figure 8. Float-zone silicon crystal puller
a) Feed rod shaft; b) Feed rod holder; c) Feed rod, polycrystalline; d) Single crystal; e) Neck; f) Seed; g) Seed holder; h) Seed shaft; i) Seal; j) To the vacuum pump; k) Camera; l) Viewing port; m) RF heating coil; n) Valve

Growing large-diameter crystals requires large amounts of energy and thus high RF voltages. To prevent sparkover at the induction coils, FZ-Si growth is carried out at higher gas pressures (> 1 bar). In contrast to CZ-Si growth, no argon flow takes place during FZ-Si growth; the FZ pulling chamber is first evacuated to high vacuum and then filled with argon to a certain pressure. The doping of silicon is realized during FZ crystal growth by the controlled addition of a doping gas (B_2H_6 or PH_3) to the argon during growth.

The monitoring and control of crystal diameter and the degree of automation of FZ-Si growth are similar to those of CZ-Si growth. Standard commercial production in 1992 (see Table 2) had crystal diameters up to 150 mm (usually ca. 100 mm). Larger diameters could be developed if they were in industrial demand.

Float-zone crystals can be pulled with higher growth rates than CZ crystals, because the solidification energy of FZ crystals is removed more quickly. With FZ growth the entire environment of the cooling crystal is cold (ca. 300 K, see Fig. 8), whereas the environment of the CZ crystal is very hot in places (melt, crucible, and furnace near 1700 K), and the growing CZ crystal receives much energy from thermal radiation.

Figure 9. Relative axial concentration variation C_x/C_0 in silicon crystals produced from starting material (melt or feed rod) in which the impurities are distributed homogeneously
A) CZ crystals (normal freezing); B) FZ crystals (final melt zone freezes according to normal freezing); in this example, total length of feed rod is 100 l, and a constant cylindrical shape and diameter is assumed for the system feed rod – FZ melt – FZ crystal
k = Distribution coefficient

The maximum growth rate depends strongly on the crystal diameter in both FZ and CZ growth. With increasing diameter the ratio between the heat-emitting surface (predominantly

the parts of the surface hotter than 1200 K) and the heat-absorbing and generating growth interface becomes smaller, and additionally, the diffusion length of the heat increases owing to increasing distance between the crystal axis and the crystal surface. The maximum growth rate decreases from about 10 mm/min at 5-mm crystal diameter to about 1 mm/min at 150-mm crystal diameter for CZ-Si growth; the corresponding values for FZ-Si growth are 12 mm/min and 2 mm/min. In industrial production, the growth rates are lower than the maximum growth rates for reasons of yield and quality.

Segregation of Impurities. The axial variation of impurity concentration in CZ- and FZ-Si crystals due to segregation is shown in Figure 9. The segregation of impurities, in particular of dopants, has important qualitative and economical effects. Silicon device manufacturers demand silicon materials with tight resistivity tolerances, but CZ-Si crystal rods meet these tolerances only in small sections of their length.

In this respect, FZ-Si growth has major economic advantages. The resistivity of a boron- or phosphorus-doped FZ-Si crystal is nearly constant over its entire length. Strong variations occur only in the seed cone and in the finally freezing melt because of the small FZ melt volume. The height and depth of the melt are only a few centimeters (near the crystal axis) and depend on the crystal diameter and the curvature of the concave solid – liquid interface. The melt volume in FZ growth is much smaller than in CZ growth and remains nearly constant during growth of the cylindrical crystal.

In CZ growth the silicon charge is melted completely at the beginning. The melt volume decreases and the dopant concentration increases continuously during crystal growth. This is valid for nonvolatile or moderately volatile dopants such as B, P, Al, and Ga. In the case of volatile dopants such as As, Sb, or In, the enrichment of the melt with dopant can be compensated or overcompensated by evaporation of the dopant. In FZ growth the enrichment of boron or phosphorus is continuously compensated by the supply of unenriched silicon.

Many attempts and developments have been made to eliminate the axial resistivity decrease during CZ-Si growth. A partial solution of this problem is to consume only a part (e.g., one-half) of the melt and then to refill the crucible by adding polycrystalline silicon chips or by immersion and melting of a polycrystalline silicon rod.

Conditions similar to those during FZ growth can be realized with small CZ melts that are fed quasi- continuously with silicon and dopant (Fig. 10). The crucible is held in a fixed position and filled with melt to a certain level. A silica baffle is suspended from the cover of the furnace and dips several centimeters into the melt. The baffle has openings above the melt level to allow purging with argon. Additionally,a conical shield covers a large part of the melt surface to prevent the backflow and condensation of SiO on the feeding tube and baffle and to reduce heat losses by radiation. The silica feeding tube reaches to a short distance above the melt. Silicon granules and dopants are fed continuously through this tube at the same rate melt is removed by the growing crystal.

Figure 10. Quasi- continuous feeding of a CZ melt with silicon granules
a) Radiation shield, graphite; b) Crystal; c) Feeding tube, silica; d) Silicon granules; e) Baffle, silica; f) Crucible, silica; g) Susceptor, graphite; h) Melt; i) Heater, graphite; j) Thermal insulation, carbon; k) Crucible shaft, graphite

The problem with this technique is that fusion energy for the granules must be supplied during crystal growth, resulting in higher temperature of the crucible walls and problems with corrosion of the silica, with oxygen content, and with dislocation-free growth. Additional problems result from silicon crystallites that "swim" underneath the baffle from outside to the growing crystal where they generate dislocations.

The fusion energy for the silicon need not be supplied to the melt from which the crystal is grown if the melt is fed with molten silicon.

Melt Flows. Constant-volume melts have the advantage that their convective flows are constant over time. On a macroscopic scale they give a constant oxygen content and a constant radial impurity distribution. Small melts have the advantage of more controllable convective flows because of their weaker thermal convection. The thermal convection in the CZ-Si melt depends on the Grashof number *Gr:*

$$Gr = \frac{g\alpha \, \mathrm{d}T h^3}{\nu^2}$$

where g is the acceleration due to gravity, α is the volume thermal expansion coefficient, dT is the temperature difference in the melt, h is the height of the melt, and ν is the kinematic viscosity.

Figure 11. Schematic of the convective flows in a CZ silicon melt; flows are both temporally and locally inhomogeneous, creating temperature and concentration fluctuations
a) Mechanically forced convection; b) Thermal convection; c) Thermocapillary (Marangoni) convection; d) Crystal; e) Diffusion layer; f) Melt; g) Crucible; h) Susceptor; i) Heat flow direction

Owing to the dependence on h^3 and dT (the temperature differences in large melts are greater than in small melts), the convective flows in large CZ-Si melts become very turbulent, unsteady, and nearly uncontrollable. The unsteady flows result in large temperature fluctuations at the solid – liquid interface and in large fluctuations in oxygen transport to the crystal.

Figure 11 shows schematically the various convective flows in a CZ-Si melt. In the classical "open" growth furnace, thermal convection is strongest. A thermocapillary convection – also called Marangoni convection – always occurs below the melt surface at the edge of the crystal and at the crucible wall. It is driven by the differences in surface tension due to differences in the melt temperature. The effects of thermocapillary convection are not well understood.

Mechanically forced convection is generated by rotation of the crystal and crucible. Crystal rotation must be used for two reasons. First, without rotation, the crystal would grow with a noncylindrical shape and dislocations would be generated; second, crystal rotation reduces the strong impurity enrichment toward the center of the crystal caused by thermocapillary convection and segregation.

The incorporation of impurities depends strongly on the thickness of the diffusion layer in the melt at the solid – liquid interface: the thicker the diffusion layer, the higher the incorporation of impurities into the crystal. The thickness of the diffusion layer is strongly influenced by melt flows.

Impurity Striations. Temperature fluctuations at the solid – liquid interface lead to unsteady growth and backmelting. These result in microscopic impurity variations in the crystal, also called impurity striations. Unsteady growth can be reduced by using a high crystal rotational velocity because, first, mechanically forced convection decreases the influence of unsteady thermal convection at the growth interface, and second, when the crystal is moved quickly over the temperature irregularities, temperature variations in the crystal are decreased owing to its thermal response time.

In general, the oxygen distribution does not correspond to the distribution of other elements; this is true on a microscopic scale as well. The effective distribution coefficient of oxygen is

nearly unity and depends only slightly on the growth rate. However, the incorporation of oxygen into the growing crystal depends strongly on the pattern of convective flows in the melt. Therefore, unsteady melt flows result in an unsteady supply of oxygen and in oxygen striations in the crystal.

Figure 12. Growth of CZ silicon with two opposing vertical (also called cusp or configured) magnetic fields

Modifying Melt Flows. Melt flows in a CZ-Si melt can be modified in several ways. In most cases, this is achieved by altering growth parameters such as crystal rotation rate, crucible rotation rate, melt dimensions, furnace dimensions, furnace construction, and so on.

A more expensive way to influence the flows in a silicon melt is by the application of magnetic fields, which interact with the free electrons of the silicon melt and retard melt flows.

The easiest way to produce a magnetic field in a CZ-Si melt is to wind a magnetic coil around the furnace vessel and generate a vertical magnetic field in the melt. However, purely vertical fields were shown to result in poor radial impurity distributions. Better results were obtained with transverse magnetic fields, which damp the melt particularly in the vertical direction. This gives a more homogeneous radial impurity distribution of both oxygen and dopant and a low oxygen content. However, the isotherms in the melt are elliptically distorted, which causes backmelting at each revolution of the crystal and rotational striations of oxygen and dopants. Transverse magnetic fields up to 4000 G with diameters up to 100 cm are applied at present.

The third and newest method is the use of two opposing magnetic fields (see Fig. 12); this is probably the best method of the three, but it is not yet fully developed. Two magnetic coils surround the furnace vessel and generate opposing vertical magnetic fields. The coils can be moved vertically to adjust the field to the requirements of the melt; this can also be done during crystal growth. The coils and the field strength are arranged in such a way that a strong field is present near the crucible wall and a weak or zero field in the melt below the crystal. Thereby, melt flows are damped near the crucible wall and the transport of oxygen from the crucible to the crystal is reduced, but they are not damped below the crystal, where mechanically forced convection may result in a homogeneous radial impurity distribution. Good radial oxygen and dopant distributions and low oxygen contents are possible with this method.

Neutron Transmutation Doping. In the case of phosphorus doping, the problem of macro- and microscopical resistivity variation in silicon crystals can be overcome by neutron transmutation doping (NTD). The isotope ^{30}Si, which is present in natural silicon at 3.1 atom %, can be transformed to ^{31}P by absorption of a thermal neutron and emission of an electron:

$$^{30}\mathrm{Si} + \mathrm{n} \longrightarrow {}^{31}\mathrm{Si} + \gamma$$
$$^{31}\mathrm{Si} \xrightarrow{2.6\,\mathrm{h}} {}^{31}\mathrm{P} + \mathrm{e}$$

In the nuclear reaction, the ^{31}Si/^{31}P atoms are displaced from their lattice sites and travel a short distance through the lattice, causing lattice defects. Annealing the crystal at ca. 1100 K restores the silicon lattice, and the ^{31}P atoms return to lattice sites.

The transformation takes place very homogeneously in silicon, because most of the neutrons pass through the silicon crystal without being captured, and each ^{30}Si atom in the crystal has nearly the same probability of capturing a neutron as of being transformed into phosphorus. Consequently, the ^{31}P atoms generated by transmutation are distributed very homogeneously in the crystal.

4.2.4. Wafer Manufacture

After they are grown, silicon crystals are not perfectly cylindrical and do not have the precise nominal diameter despite highly automated and sophisticated crystal pulling. There are always lines of small nodes (at ⟨100⟩ crystals) or facets (at ⟨111⟩ crystals) on the crystal surface parallel to the crystal axis and small variations in crystal diameter. Therefore, the crystals are grown slightly larger in diameter and then ground precisely to cylinders of the stated diameter. To allow crystal-oriented positioning of the wafers in subsequent process steps, the wafers must have flats or notches at special crystallographic sites. For this purpose, planes or notches with defined crystal orientations (e.g., ⟨100⟩, ⟨110⟩, ⟨112⟩) are ground into the cylinders. After grinding, the ingots are polish-etched to remove grinding damage and to reduce wafer breakage on slicing.

Figure 13. Inner-diameter (ID) sawing machine for slicing silicon
a) Crystal tilting; b) Crystal support and vertical feeding; c) Crystal; d) Saw-blade drive unit; e) ID saw blade; f) Horizontal crystal feeding

Depending on the application of the wafers, the ingot is cut perpendicular to the crystal axis or with a well-defined misorientation of several degrees. These off-axis wafers, after polishing, are normally used as substrates for epitaxial processes. Slicing is performed with inner-diameter saws (see Fig. 13), the saw blade of which is a 0.1-mm-thick high-grade steel foil clamped under high tension between two steel rings. The steel foil has a large circular opening in its center, the edge of which is covered with small diamonds attached to the foil by a galvanic nickel layer. During sawing, the steel foil rotates at ca. 2000 rpm and consumes 0.3 mm of the ingot length (0.3-mm cutting loss). This method generates the flattest and most parallel cuts, and allows the cutting of silicon wafers down to ca. 150-µm thickness with little wafer breakage. For the manufacture of electronic devices, wafers with thicknesses between 150 and 1000 µm are cut.

Figure 14. Polishing machine for silicon wafers
a) Polishing slurry feeding; b) Polishing pressure control; c) Wafer carrier; d) Wafers; e) Polishing plate; f) Drive unit

After cutting, the wafers are edge-rounded in special machines, which enable the grinding of different round forms. Edge rounding substantially reduces chipping of the edges in subsequent process steps, imparts a higher mechanical strength to the wafers, and prevents the so-called epi- crown (irregular outgrowth of silicon at the wafer edge) in epitaxial deposition processes and the piling up of photoresist at the edges.

Especially for the mask printing techniques of modern VLSI (very large scale integrated) device manufacturing, the flatness and parallelism of the wafers must be improved by a lapping step. The silicon wafers are lapped between two

large counterrotating steel disks, whereby the wafers are held and led by a lapping carrier. A suspension of an abrasive (a powder of silicon carbide, aluminum oxide, or a mixture of oxides with tightly specified grain size) is added to the process. After lapping, the wafers are etched to remove mechanical damage and then polished.

Figure 14 shows a schematic and Figure 15 a photograph of a polishing machine for silicon wafers. Nowadays, polishing methods basically involve the combined action of chemical and mechanical forces. The polished wafer surface must be free of any residual damage, because such damage may cause stacking faults during subsequent oxidation treatments. Another very stringent demand on surface quality stems from modern photolithographic processing techniques. The polished surface must lie within the depth-of-focus range of the optical systems used to project a masking pattern on the photoresist cover-ing the surface of the wafer.

With the above technology, 200-mm-diameter wafers with both total flatness and total thickness variation of $< 1\,\mu m$ are obtained. After polishing, a careful multistep cleaning process follows that yields a wafer free of particles ($> 0.2\,\mu m$) and residues.

4.2.5. Epitaxy

In epitaxy a crystallographically oriented film is grown as an extension onto an oriented crystal substrate. The growth of an epitaxial film or layer may be realized either by chemical vapor deposition, by physical vapor deposition (e.g., molecular beam epitaxy, MBE), or by liquid-phase epitaxy (LPE). In industrial silicon epitaxy, chemical vapor deposition is employed [18], [19]. With this method, homoepitaxial silicon layers with thicknesses of $0.5 - 120\,\mu m$ are deposited on perfectly polished single- crystal silicon wafers or substrates. The epitaxial or epi layers extend the crystal structure of the substrate exactly and differ only in resistivity and dopant. For device manufacturing, resistivities of ca. $0.03 - 50\,\Omega \cdot cm$ are generated in the layers by doping, mainly with boron, phosphorus, and arsenic.

Epitaxy is performed both on the whole wafer surface (after polishing and prior to device manufacturing) and on small areas of structured wafers (during device manufacturing). In most cases, only one layer is deposited, but in some cases two or three additional layers of different thickness, resistivity, and dopant are deposited. The reasons for using epitaxial layers in device technology are numerous and various [18], [19]. The use of vapor-phase epitaxy in the semiconductor industry began in the early 1960s.

Epitaxial deposition of silicon is in principle the same process as the chemical vapor deposition used for the production of high-purity polycrystalline silicon (see Section 4.2.2). It is carried out at about the same temperature (usually ca. 1400 K) but with a lower growth rate and more precise control. Epitaxial deposition is possible down to ca. 1100 K. At lower temperature the silicon layer becomes polycrystalline or amorphous. The chlorosilanes $SiCl_4$, $SiHCl_3$, and SiH_2Cl_2 are used most frequently as silicon sources, with hydrogen as a reducing gas. The overall simplified reactions are

$$SiCl_4(g) + 2\,H_2(g) \rightleftharpoons Si\,(s) + 4\,HCl\,(g)$$

$$SiHCl_3(g) + H_2(g) \rightleftharpoons Si\,(s) + 3\,HCl\,(g)$$

$$SiH_2Cl_2(g) \rightleftharpoons Si\,(s) + 2\,HCl\,(g)$$

By using trichlorosilane, $SiHCl_3$, and hydrogen at 1400 K, an epitaxial silicon layer grows at about $5\,\mu m/min$. Table 3 gives epitaxial growth rates for various silanes and temperatures [19].

Table 3. Chemical vapor epitaxial growth of silicon films

Silane	Temperature range, K	Attainable growth rate, µm/min
$SiCl_4$	1420 – 1530	0.4 – 15.0
$SiHCl_3$	1370 – 1480	0.4 – 2.0
SiH_2Cl_2	1320 – 1430	0.4 – 3.0
SiH_4	1220 – 1330	0.2 – 0.3

Prior to deposition, the native oxide on the silicon wafer is removed by baking in hydrogen:

$$SiO_2(s) + Si\,(s) \longrightarrow 2\,SiO\,(g)$$

After that, a brief hydrogen chloride etch is generally applied to remove impurities from the wafer surface. During epitaxy, the wafer is held by a susceptor made of high-purity graphite coated with a layer of silicon carbide. The graphite susceptor is also hot during deposition

Figure 15. View of a polishing machine for silicon wafers

Figure 16. Three types of epitaxy reactors for silicon wafers

and therefore is also covered with a silicon layer after epitaxy. This unwanted silicon layer is removed by etching with hydrogen chloride. In this way, deposition conditions are identical for each wafer.

To generate electrical doping in the epi layer, gases such as B_2H_6, PH_3, and AsH_3 are added to the chlorosilane – hydrogen mixture. The doping gases decompose and the doping elements are absorbed or dissolved by the growing silicon layer. Because of their low diffusivity, the dopants diffuse only a short distance into the silicon substrate. Epitaxial layers with net charge carrier concentrations in the range of $10^{14} - 10^{20}/cm^3$ can be obtained readily. Figures 16 and 17 show schematically some epitaxial reactors.

4.2.6. Characterization

After crystal pulling, the properties of the silicon crystals, particularly the CZ-Si crystals for megabit devices, must be measured and tested in manifold respects. A great and constantly growing number of measuring and testing methods are employed on silicon. The extent of their application depends on the type and use of the respective material. The most common measuring and testing methods are described briefly below.

Bulk properties:

1) Macroscopic axial and radial distribution of resistivity by two- and four-point probe measurements
2) Microscopic resistivity distribution by spreading resistance measurements
3) Oxygen and carbon concentrations by Fourier transform infrared absorption (FTIR) measurements
4) Oxygen content in samples with high dopant concentration by gas fusion analysis (GFA)
5) Oxygen precipitation behavior in standardized annealings by FTIR measurements and microscopic visual or instrumental determination of the precipitate density and distribution
6) Determination of the content of stacking fault nuclei by oxidation tests and microscopic analysis
7) Testing of the gate oxide integrity (GOI) by a gate oxidation and a subsequent electrical measurement
8) Trap analysis by measuring the minority carrier diffusion length [e.g., with the surface photovoltage (SPV) method]
9) Concentrations of N, B, Al, Ga, P, As, Sb, C−O complexes, thermal donors, etc., by low-temperature (ca. 8 K) FTIR measurements
10) Concentration of electrically active impurities (e.g., metals) and compounds (e.g., FeB) by deep-level transient spectroscopy (DLTS)
11) Concentration of impurities by instrumental neutron activation analysis (INAA; detection limit = 0.00001 – 10 ppba depending on the element)

Geometrical and structural wafer properties:

1) Thickness, parallelism, and flatness by diverse mechanical, optical, or electrical measurements ($\geq 0.1\ \mu m$)
2) Chipping off, scratches, spots
3) Number and size of particles $> 0.15\ \mu m$ on the wafer surface
4) Roughness and haze on the surface by visual or instrumental optical inspection

Purity of the wafer surface: determination of diverse elements and compounds by

1) Inductively coupled plasma mass spectrometry (ICPMS)
2) Total reflection X-ray Fourier analysis (TRXFA)
3) Inductively coupled plasma Auger electron spectroscopy (ICPAES)
4) Vapor-phase decomposition Auger electron spectroscopy (VPDAES)
5) Ion chromatography (IC) and other methods.

4.3. Solar Silicon

Detailed information on solar silicon and its production is given in [5].

A distinction can be made between solar cells for terrestrial applications and solar cells for extraterrestrial applications. In the latter case, the efficiency (output per square meter) is the most important factor; therefore, the best CZ silicon single- crystal qualities are used. Float-zone silicon is not used for extraterrestrial applications because it degrades too strongly on exposure to cosmic radiation, eventually reaching a lower efficiency than CZ silicon. The CZ silicon is more stable owing to its high oxygen content (ca. 15 ppma).

In the case of terrestrial photovoltaic solar cells, the prevailing opinion was initially that solar silicon should be as cheap as possible, and this led to the development of low-priced silicon of low efficiency for solar applications. However, the majority of the costs of a solar module come not from the silicon wafers but from costs that are proportional to the area of the module and are difficult to reduce. At present, about 30 % of the module costs result from the silicon wafers, 30 % from the manufacturing of the solar cell structures, and 40 % from module costs

(metals, glass, machining, etc.). Therefore, developments concentrate increasingly on the production of high-efficiency silicon of moderate or low price. High-efficiency silicon means that the purity and crystal quality of the material must be similar to those of silicon for electronic applications (i.e., monocrystalline and free of dislocations and microdefects). Consequently, solar-grade silicon and electronic-grade silicon will be produced by similar methods in the future.

This trend can already be seen in the development of the solar energy market. The market shares of amorphous silicon and nonsilicon solar materials such as $CuInSe_2$ and CdS are decreasing, while the market shares of multicrystalline silicon and, in particular, single- crystal silicon are increasing.

Table 4 shows the situation of the photovoltaic market in 1990 [20–22]. Photovoltaic (PV) modules for 48 MW_p (p = peak) were produced in total. The value of these PV moduls (ca. $\$400\times10^6$) was about 0.5 % of the value of the electronic devices made from silicon (ca. $\$90\times10^9$).

Table 4. Solar silicon market in 1990

Type of material	Efficiency, %	Module price∗, $/$W_p$	Production MW_p	Share, %
Mono-Si	ca. 15	ca. 4.5	21	44
Multi-Si	ca. 13	ca. 4.5	12	25
a-Si : H	ca. 5	ca. 4.5	15	30
Others		in development		ca. 1

∗ The selling prices are coupled to the output of the modules and not to the manufacturing cost.

4.3.1. Crystalline Silicon

At present, the industry uses the same starting material (high-purity CVD polycrystalline silicon) for the production of crystalline solar silicon as is used for the growth of single- crystal silicon for electronic devices. The production of CVD polycrystalline silicon is described in Sections 4.2.1 and 4.2.2. In 1990, ca. 8000 t of CVD polycrystalline silicon was produced, of which ca. 7000 t was consumed for the production of electronic devices, ca. 700 t for the production of solar cells, and the rest for other applications.

Monocrystalline Silicon. For terrestrial solar cells, CZ and FZ silicon single crystals of $0.5-5\,\Omega\cdot$cm, mostly p-type and sometimes n-type, are used. Float-zone silicon has a market share of about 3 % and is used only for manufacturing very high-efficiency solar cells for light concentrators.

For extraterrestrial applications, CZ crystals of higher resistivity ($7-13\,\Omega\cdot$cm) are used to reduce the degradation of the material by cosmic radiation. The resistivity chosen results from the optimization of the internal resistivity of the solar cell and the diffusion length of the minority charge carriers that are generated by photons and form the electrical current in the solar cell. Increasing the internal resistivity and decreasing the diffusion length reduce the efficiency of a solar cell. The diffusion length of the minority charge carriers is reduced by "traps" that capture the carriers and by too high a dopant concentration. Traps are formed by impurities (e.g., transition metals such as Fe, Mn, Cr, V, and Ti), by small impurity precipitates, and by crystal defects having dangling bonds.

Single- crystal silicon for solar cells is produced in the same way as that for electronic applications (see Section 4.2). The cylindrical silicon crystals are cut to square ingots and then sawed into slices. Square slices give a more complete area covering than round slices.

At present, the efficiency of PV modules made from monocrystalline silicon reaches 18 % in industrial production [23] and 24 % in laboratory production [24].

Multicrystalline Silicon. Multicrystalline silicon is produced by ingot or sheet crystallization.

Figure 18. Equipment for semicontinuous production of multicrystalline silicon ingots by mold casting
a) Crucible; b) Piston; c) Heater; d) Mold; e) Heating; f) Cast ingot; g) Rotating cooling plate; h) Base plate

Ingot Crystallization. Several methods are used to produce multicrystalline silicon ingots:

1) Melting in a crucible and crystallization onto a cold plug, which is immersed in the melt and then withdrawn
2) Melting and solidification in the same crucible
3) Melting in a crucible, and casting and solidification in a mold (see Fig. 18)
4) Quasi-continuous melting in and pulling downward through a so-called cold crucible, which is open at the bottom (see Fig. 19)
5) Quasi-continuous casting through a cold crucible or graphite shaper analogous to (4)

Figure 19. Cold crucible induction casting for multicrystalline silicon ingots
a) Valve; b) Granule feeder; c) Silicon granules; d) Cooling water; e) Auxiliary heater; f) Ingot puller; g) Ingot; h) Vacuum port; i) Induction coil; j) Inert gas inlet

Method (1) is not used for several reasons. Method (2) yields a good crystalline structure owing to its very slow crystallization but includes high crucible costs (crucible is not reusable). Method (3) is the most economical (reusable mold) and also yields good crystal quality. Methods (2) and (3) both yield square ingots, which is a major economic advantage (100 % area coverage).

The ingots must be cut into thin slices (200 – 500 µm thick) for manufacturing solar cells. At present, inner-diameter saws (see Fig. 13) are generally used. However, multiple-wire sawing (Fig. 20) is gaining in importance. Multiple-wire sawing will be the slicing technique of the future for solar silicon because it results in lower material losses and can cut thinner slices.

Figure 20. Multiple-wire slurry slicing technique
A single cutting wire is wound onto a delivery spool. The wire is arranged in multiple loops around grooved drive and idle rollers and fixed to the take-up spool

The current efficiencies of multicrystalline solar cells reach 15 %.

Sheet crystallization. The advantage of sheet crystallization is that slicing, which causes high machining costs and material loss, is unnecessary. For economic reasons, sheet crystallization must be carried out at a very high growth rate. However, with such a growth rate, the segregation coefficients of the impurities become unity, and the impurities from the bulk and the surface of the starting polysilicon are incorporated completely into the silicon sheet. In contrast, at the low growth rates in single-crystal pulling or ingot crystallization the impurity concentration of the silicon is reduced drastically (e.g., by a factor of 10^5 for iron). Therefore, the starting silicon for sheet growth must be of a much higher purity than that for crystal or ingot growth.

Figure 21. Continuous production of silicon ribbons
a) Heater; b) Piston; c) Crucible; d) Heater; e) Die; f) Foil carrier; g) Heated cylinder; h) Ramp; i) Cooled cylinder; j) Separator

A second disadvantage is that the very high growth rate leads to poor crystal quality (high density of dislocations and grain boundaries). The higher content of both impurities and crystal defects results in lower solar cell efficiency. These two major drawbacks may not be overcome in the future.

Figures 21 and 22 give examples of multicrystalline silicon sheet growth. Many other methods exist for producing such materials [5], [25].

a) Silicon ribbon; b) Die; c) Crucible; d) Melt

4.3.2. Amorphous Silicon

Amorphous silicon is often abbreviated to a-Si : H in contrast to c-Si for crystalline silicon. The H in a-Si : H stands for hydrogen, which is needed to neutralize the detrimental dangling bonds. Most of the a-Si : H is used for photovoltaics and is prominent in consumer and low-power applications. In addition to photovoltaics, a-Si : H is employed for electrophotography, in photodetectors, and in accumulation-model field-effect transistors and other electronic devices. In particular, it can be used in integrated functions.

The a-Si : H solar cell is a typical thin-film device. The film is ca. 1 µm thick and is manufactured in large areas in integrated thin-film deposition lines (CVD at 470 – 530 K; see Section 4.2.2). The stabilized efficiency of modules in the field is ca. 5 %. Multijunction devices incorporating a-Si : H/a-Si : H tandems or a-Si : H/a-Si : H/a-Si, Ge : H triple junctions are under development for a stabilized efficiency of 8 % [22].

5. Silicides

Silicides are compounds of silicon with a metal. Figure 23 shows the silicide phases, arranged according to the position of the metal in the periodic table [26], [27].

Many metals of groups 1 – 3 and most transition metals form silicides. Physical properties and structures of silicides are summarized in [26], [27]. The corresponding binary phase diagrams often show the existence of several compounds, having mainly nonstoichiometric compositions and intermetallic character.

Production processes for silicides are based on the following reactions:

1) Fusing or sintering of the metal with silicon:

$$M + Si \longrightarrow MSi$$

2) Reduction of metal oxides by silicon:

$$MO + Si \longrightarrow MSi + SiO_2$$

3) Reaction of metal oxides with SiO_2 and carbon:

$$MO + SiO_2 + C \longrightarrow MSi + CO$$

4) Aluminothermic reaction:

$$MO + SiO_2 + Al \longrightarrow MSi + Al_2O_3 + slag$$

Figure 23. Silicides in the periodic table [26]

Silicides have an iron-gray, metallic luster and are resistant to oxidation. Most of the compounds shown in Figure 23 are currently of only academic interest. The silicides of molybdenum, iron, and calcium have achieved commercial significance.

Molybdenum disilicide, a brittle alloy that is very resistant to oxidation, is used as an alloy for heating conductors. It is converted to cermets, from which resistors are then made. Ferrosilicon and calcium silicon are produced in large quantities for use as alloying and refining reagents in steelmaking and casting.

6. Ferrosilicon [28], [29]

The term ferrosilicon [*8049-17-0*] refers to iron – silicon alloys with Si contents of 8 – 95 %.

Table 5 lists the composition of commercial ferrosilicons.

FeSi 75 is commercially the most important, although FeSi 45 is still produced in large quantities for the North American market. Alloys containing > 95 % silicon are classified as silicon metal.

Physical Properties. The Fe – Si phase diagram (Fig. 24) shows the existence of four compounds: Fe_2Si, Fe_5Si_3, FeSi, and $FeSi_2$ [30]. Commercial alloys differ from the compounds shown in the phase diagram with regard to their stoichiometry.

During solidification of the standard grade, FeSi 75, silicon crystallizes initially, followed by solidification of the ξ-phase – the high-temperature phase of $FeSi_2$ – at 1207 °C. FeSi 45 is composed of initially separated FeSi and $FeSi_2$, which is stable below 955 °C [31].

Transformation of the ξ-phase to stable $FeSi_2$ is accompanied by an increase in volume, which can lead to disintegration of the alloy in the range of 45 – 65 % silicon. The transformation and thus the disintegration can be suppressed by supercooling (i.e., rapid solidification in shallow molds).

Structural data for the iron silicides are summarized in Table 6. Table 7 lists the densities and melting ranges of commercial alloys.

Table 5. Composition of ferrosilicons (ISO 5445)

FeSi	cubic	$a = 448.9$
$FeSi_2$	tetragonal	$a = 269.2$ $c = 513.7$

Table 7. Density and melting range of commercial FeSi alloys

Alloy	ϱ, g/cm^3	Melting range, °C
FeSi 10	7.3	1280 – 1350
FeSi 25	6.5	1270 – 1350
FeSi 45	5.1	1250 – 1350
FeSi 75	3.2	1250 – 1350
FeSi 90	2.5	1300 – 1400

Raw Materials. Pure quartzes with SiO_2 content $> 98\,\%$ are used for the production of FeSi 45 to FeSi 90. Such quartzes occur naturally as pebbles or rock (vein quartz, quartzite). Quartz sands are processed into briquettes, in which the reducing coal required for a quasi-self-fluxing burden can be incorporated. For good gas flow through the furnace, the starting materials should be free of fine particles, which also requires that they remain dimensionally stable on heating and do not decrepitate too early.

Depending on the location, high-quality iron ore or scrap iron is used as the iron source. In industrialized countries, washed and dried unalloyed steel turnings are generally used.

Flaming coals with low ash content, metallurgical coke, high-temperature brown coal coke, petroleum coke, brown coal briquettes, or wood chips are employed as reducing agent, depending on availability. In calculating the amount of reducing agent required, the carbon resulting from consumption of the Söderberg electrodes must be taken into account; the electrodes supply 5 – 10 % of the total requirement.

The trend is toward the use of finer-grained quartz and coal. For quartz (previously 15 – 100 mm) the particle size now used is 8 – 40 mm; for coal, 2 – 20 mm.

Production. Ferrosilicon is produced in three-phase, submerged arc furnaces with power consumptions of 10 – 70 MW, corresponding to an annual capacity between 9×10^3 and 60×10^3 t per furnace.

Figure 25 shows a schematic of such a furnace. With few exceptions, production is carried out in open furnaces, which allow the burden surface to be poked with stoker machines to prevent crust formation and thus maintain uniform gas flow through the furnace. In modern furnaces the furnace casing can be rotated to reduce encrustation in the lower areas.

Closed furnaces must be built with a rotating furnace vessel to avoid sintering of the burden, since stoker machines can no longer be used. Closed furnaces operate more efficiently (cheaper) because the carbon monoxide gas formed can be used. However, this requires a more elaborate construction of the furnace: with a rotatable hearth and extensive dedusting of the hot off-gases [32].

Generally, large furnaces with capacities of > 40 MW present additional construction and operational problems. The thermal stress of the refractory materials and the off-gas losses also increase because these furnaces have higher operating temperatures [33], [34].

Reactions in the furnace occur according to the simplified scheme:

$$SiO_2 + 2\,C \longrightarrow Si + 2\,CO$$

$$Fe + Si \longrightarrow FeSi$$

Side reactions also occur that result in a lower yield of the desired product, especially when insufficient carbon is used:

$$SiO_2 + C \longrightarrow SiO + CO$$

$$SiO_2 + Si \longrightarrow 2\,SiO$$

Gaseous SiO is oxidized by atmospheric oxygen at the burden surface to give SiO_2 dust, which is carried out of the furnace with the off-gas.

An excess of carbon leads to the formation of SiC, which also lowers the yield.

Specific material and energy requirements for the production of FeSi 45 and FeSi 75 are summarized in Table 8.

Table 8. Specific material and energy consumption for FeSi production

	FeSi 45	FeSi 75
Quartz, kg/t	1200 – 1300	1800 – 2000
Iron turnings, kg/t	550 – 650	230 – 260
Carbon, kg/t	450 – 520	700 – 900
Söderberg paste, kg/t	40 – 50	55 – 70
Energy consumption, kW · h/t	5800 – 6500	8500 – 10 000

Heating the batch to the reaction temperature of up to 1800 °C is achieved mainly by electrical energy (ca. 80 %). The energy uptake of the batch depends on the so-called hearth resistance, whereby the conductivity of the FeSi burden is provided mainly by the coal. Thus, changing the type of coal influences the resistance. The grain size also plays a role: the smaller the grain, the higher is the resistance. The hearth resistance automatically regulates the depth of insertion of the Söderberg electrodes and thus the power consumption of the furnace. A uniformly high hearth resistance and low electrodes are desirable.

The liquid alloy, that accumulates in the hearth is tapped off to pouring ladles at regular intervals (about once an hour) and poured into shallow molds.

Ferrosilicon production is a slag-free process, which means that all the impurities present in the raw materials are transferred to the product. To obtain high purities the alloy must be purified by further treatment outside the furnace.

Aluminum and calcium impurities are removed by oxidation:

1) By injection of gaseous oxygen through immersed lances or through nozzles or sparging blocks in the base of the pouring ladle
2) By treatment with oxidizing siliceous slag, which can be stirred or blown in

Treatments used to obtain the lowest aluminum and calcium concentrations (in the extreme case, 0.02 % max.) also result in silicon losses. The silicon content for these grades drops from 75 to ca. 65 %.

Due to the low affinity of titanium for oxygen, the content of titanium impurities cannot be lowered metallurgically. Low Ti contents must

Figure 25. Submerged arc furnace
a) Furnace casing with lining (rotatable); b) Electrodes; c) Transformers; d) Secondary power supply; e) Raw material bunker; f) Charging pipes; g) Stoker machine; h) Burning-out unit; i) Tapping-off ladle

be obtained by using raw materials that contain as little titanium as possible.

Environmental Protection. Silicon monoxide vapor is formed in the reduction process. The SiO is oxidized in air to produce extremely fine SiO_2 dust (particle size 0.1 – 1 µm), which is carried out of the furnace with the off-gas. Furthermore, small amounts of fine particles from the burden are also entrained. A total of 250 – 350 kg of dust is produced per tonne of FeSi 75 [35].

The off-gas from the furnace can be cleaned in filter chambers (bag filters) to the maximum values allowed by TA Luft (20 mg/m^3). The collected dust is sometimes dumped but is now mainly sold as a raw material. Pure SiO_2 dusts are used as cement additives, for example [36], [37].

Since the FeSi process is slag free, it has the advantage of having no slag that must be disposed of.

Quality Specifications. Quality requirements and terms of delivery are summarized in ISO 5445 (see Table 5) and DIN 17 560. In addition, numerous customer specifications exist, some of which require drastically reduced impurity contents. The sieve analysis of ferroalloys is set out in ISO 4551; sampling is described in ISO 4552; and chemical analysis, in ISO 4139 and ISO 4158. Recognized analysis methods are also described in [38–40].

Storage, Transport, and Toxicology. Ferrosilicons produce hydrogen on contact with water. Alloys containing 30 – 70 % Si are classified as dangerous substances, Class 4.3, for transport by road and rail according to GGVS/GGVE and RID/ADR. Alloys with < 30 % and > 70 % Si are excluded from this regulation for land transportation. All commercial FeSi alloys are classified as dangerous goods, Class 4.3, for transportation by ship (IMDG Code) and by air (UN no. 1408, IATA-DGR: Class 4.3).

Ferrosilicon itself is nontoxic. For handling the dust the general MAK values for fine dust (6 mg/m^3) are applicable [41], as well as the usual safety measures such as goggles and face masks.

On contact with water, traces of toxic gases such as phosphine can be formed by reaction with slag adhering to the ferrosilicon. However, if stored in ventilated rooms in accordance with regulations, the critical MAK concentrations are rarely attained (PH_3: MAK 0.1 ppm) [41].

Uses. Approximately 75 % of the FeSi produced is used in the steel industry, where a requirement of 3 – 3.5 kg of FeSi 75 per tonne of steel can be considered normal. For melting almost all grades of steel, silicon is added as a deoxidizer and alloying agent. Silicon binds oxygen dissolved in steel melts, leading to noncritical concentrations. To increase this effect, FeSi is generally added together with other deoxidizers such as aluminum, calcium, and manganese.

Silicon that is not consumed in deoxidation dissolves as an alloying element in the steel and increases its strength and yield point [42]. Conventional construction steels contain 0.2 – 0.4 % silicon. More highly alloyed grades include tool steels, in which silicon improves the hardenability and wear resistance; hot-work steels that contain silicon for better tempering properties; spring steels (up to 2 % Si); and transformer and electro steels (up to 4.5 % Si). Low hysteresis losses are characteristic of the latter materials. Since the magnetic losses depend on the purity of the steel, high-purity FeSi, with drastically reduced content of aluminum, carbon, and titanium, is used.

Foundries consume almost 25 % of the ferrosilicon produced worldwide. Normal cast iron contains 2 – 3 % silicon for improved precipitation of graphite and increased strength.

Ferrosilicon alloys are also used as carrier alloys for metals such as barium, strontium, calcium, and titanium, usually in amounts of 2 – 4 %. These treatment alloys for gray cast iron are added to the ladle or mold to improve the precipitation of graphite. Ferrosilicon is also the prealloy for FeSiMg alloys; magnesium causes the formation of spherical graphite in spherulitic graphite iron.

Economic Aspcects. In 1990, world consumption of ferrosilicon, calculated as FeSi 75, was 3.4×10^6 t, which compared to a capacity of 5.5×10^6 t. Thus capacities were utilized only to ca. 62 %. Usually, the rate of utilization varies between 65 and 75 %. Thus, the economic situation at the beginning of the 1990s was characterized by marked pressure on prices and by the closure of unprofitable operations. However, new capacities of ca. 250×10^3 t/a are now planned, with almost 200×10^3 t/a in Venezuela alone.

The choice of plant location depends less on the raw materials (quartz, coal) than on the availability of cheap electricity. Production is spread worldwide; the CIS and China are important producers (each with a capacity of ca. 10^6 t/a), followed by Norway, the United States, and Brazil (each ca. 0.5×10^6 t/a).

Figure 26. Calcium – silicon phase diagram [44]

7. Calcium Silicon [43]

Like FeSi, calcium silicon [*8049-17-0*] is produced carbothermally in submerged arc furnaces and is consumed in the iron and steel industry.

Physical Properties. The Ca – Si phase diagram (Fig. 26) shows the existence of three compounds [44]: Ca_2Si (cubic, $a = 474$ pm), CaSi (orthorhombic, $a = 391$ pm, $b = 459$ pm, $c = 1080$ pm), and $CaSi_2$ (hexagonal rhombohedral, $a = 1040$ pm, $\alpha = 21.5°$). Commercial CaSi contains ca. 30 % calcium and 60 % silicon; the remainder is iron and impurities. The alloy solidifies mainly as $CaSi_2$ with small amounts of primary and secondary eutectically precipitated silicon. The density of the commercial alloy is 2.2 g/cm^3, and its melting range is 1050 – 1150 °C.

Raw Materials and Production. The raw materials for the production of CaSi are quartz, lime, and coal. Whereas calcium carbide was formerly used as the source of calcium, it has now been replaced by lime with the following approximate specifications: CaO 94 – 97 %, CO_2 1.5 – 3 %, H_2O 0.5 – 1.5 %.

The requirements for quartz and coal, as well as the particle size of the burden, correspond to those of ferrosilicon production.

The three-phase submerged arc furnaces generally used for the production of CaSi are similar to the furnaces used for the production of FeSi (see Fig. 2). In practice, CaSi and FeSi are also produced alternately in the same furnace. Calcium silicon is produced only in open furnaces whose power consumption is 8 – 30 MW, corresponding to a capacity of $(6-20)\times 10^3$ t/a. The basic reaction of the commercial process is as follows:

$$CaO + 2\,SiO_2 + 5\,C \longrightarrow CaSi_2 + 5\,CO$$

In practice the processes are very complex. The process is sensitive to variations in the amount of reducing agent, which may also occur locally in the burden. An excess of carbon in the burden results in the formation of SiC and CaC_2, which in the extreme case leads to the clogging of the furnace. The use of too little carbon results in the formation of lime – silicate slags that are difficult to reduce and are tapped with the metal, which lowers the capacity of the furnace.

Even with correct operation, up to 30 % of slag is carried out with the CaSi. The slag, which is only slightly denser than CaSi, is separated after being tapped off into the pouring ladle. The slag sinks to the bottom, and the metal is then decanted by pouring into shallow molds. Some companies use a cascade of four to five tapping-off molds, which results in refinement because the slag preferably remains in the upper molds and the lower ones contain very pure metal. Careful separation from slag is the only feasible method for refining CaSi. The oxidative treatment used for FeSi is not possible because calcium has a high affinity for oxygen.

The slag, which also contains CaC_2, is processed and recycled to the furnace.

Typical values for the specific material and energy requirements of the CaSi process are as follows:

Quartz	1500 – 1 800 kg/t
Lime	550 – 700 kg/t
Coal	680 – 800 kg/t
Recycled slag	250 – 300 kg/t
Söderberg paste	80 – 100 kg/t
Power consumption	9800 – 13 000 kW · h/t

Environmental Protection. The large amount of dust generated in the CaSi process (up to 300 kg per tonne of CaSi) is a result of vapor losses of SiO and calcium. Both components are oxidized in air and carried out of the furnace with the off-gas, from which they are separated in bag filters. The dust, which consists of ca. 60 % SiO_2 and 30 % CaO (remainder: MgO, carbon, Fe_2O_3), is dumped.

Since all of the slag is reintroduced to the process, none remains to be disposed of.

Quality Specifications. The specifications for standard-grade commercial CaSi are summarized in Table 9. A number of multicomponent CaSi-based alloys contain up to 30 % aluminum, manganese, barium, titanium, magnesium, mischmetal, or iron. These compositions are often specified by the customer and are not defined in standards.

DIN 17 580 also defines procedures for analysis, testing, and arbitration [39], [45], [46].

Storage, Transport, and Toxicology. On contact with water, acid, or base, CaSi can produce hydrogen. The reaction proceeds extremely slowly with pure water and the alloy is therefore not classed as a hazardous substance in most countries (GGVS/GGVE) for transport by road.

For sea and air transport, CaSi is classed as a hazardous substance, Class 4.3 (IMDG-Code; UN no. 1405). Since fine CaSi dusts are explosive, inert gases (nitrogen or argon) must be used for pneumatic transport. The critical oxygen content for carrier or protective gases is 8 %.

Calcium silicon should be stored in dry, ventilated rooms. On contact with moisture, slag impurities can release small amounts of phosphine, although with correct storage the concentrations are not critical.

Uses. Calcium silicon is used in steelmaking as a deoxidizer and desulfurizer, as well as for

Table 9. Composition of CaSi (DIN 17 580)

Name	Symbol	Material no.	Composition, wt %					
			Ca	Ca + Si (min.)	C (max.)	Al (max.)	P (max.)	S (max.)
Calcium – silicon	CaSi	0.3650	29 – 33	90	1.20	1.80	0.070	0.060
Calcium – silicon, low C	CaSiC 50	0.3655	29 – 33	90	0.50	1.80	0.070	0.050

the modification of nonmetallic inclusions [47], [48].

Calcium is the active element in the alloy due to its high affinity for oxygen and sulfur; silicon serves as a carrier element and is alloyed in the steel melt, analogous to FeSi (see page 27).

The efficiency of calcium is very low if the alloy is added in lumps because of the high vapor pressure of calcium at the utilization temperature (p_{Ca} at 1600 °C: 0.2 MPa) and the low solubility of calcium in molten iron (max. 0.03 %).

The efficiency has been improved by the development of injection techniques. Calcium silicon powder is blown deep into the steel melt through immersion lances, or CaSi-filled hollow wires are coiled rapidly into the pouring ladle. These techniques produce very good metallurgical results and are rapidly replacing conventional addition of the alloy as lumps.

The modification of inclusions by calcium improves the fluidity of steel in automated continuous casting plants. The calcium liquefies the suspended solid inclusions of aluminum oxide that are always present in aluminum-killed steels. Furthermore, the material properties of the steel are improved: the calcium aluminates formed are largely undeformable in the solidified steel and allow high isotropy of the material properties to be maintained after working of the steel.

Economic Aspects. The amount of CaSi required by the steel industry has decreased during the 1980s due to changes in process technology: the very efficient injection techniques, especially the cored wire process, greatly reduce the amount of CaSi required per tonne of steel.

In spite of the wide range of uses, world consumption fell from ca. 100×10^3 t/a in 1981 to ca. 80×10^3 t/a in 1991. In the Western steelproducing countries, ca. 50 % is used in the form of filled wire, and this fraction will increase further.

Production capacity is estimated to be 120×10^3 t/a, distributed evenly among the former Eastern-bloc countries, South America, and Western Europe.

1. Introduction

Although silicon carbide has been an industrial product for over 100 years, it is still as important as ever, and developments have led to further new applications. This success is due to silicon carbide's special chemical and physical properties, especially its high chemical resistance, its great hardness, and its semiconducting properties. It is consequently used in the production of abrasives, refractory materials, heating elements, voltage-dependent electrical resistors, light-emitting diodes, and structural ceramic components. Silicon carbide also has the ability to dissolve in molten iron, and it is therefore used in ferrous metallurgy as an alloying and deoxidizing agent.

History [1,2]. BERZELIUS first reported the formation of silicon carbide in 1810 and 1821. It was later rediscovered during various electrothermal experiments (DESPRETZ, 1849; MARSDEN, 1881). However, it was ACHESON who first recognized the potential industrial importance of silicon carbide and exploited it. In the summer of 1891, ACHESON passed a high electric current through a mixture of powdered coke and clay. He noticed some very hard, shiny crystals on the carbon electrode that served as electrical supply. He assumed that these were a compound of carbon with corundum, and named the material carborundum. However, the chemical analysis carried out by ACHESON's coworker MÜHLHÄUSER showed that these crystals consisted of carbon and silicon in the atomic ratio 1: 1, i.e., it was silicon carbide, with the chemical formula SiC. ACHESON soon discovered that these crystals had much better abrasive properties than the emery powder then in general use, and he founded the Carborundum Company in September 1891 for the production of silicon carbide. ACHESON protected his production process, which used a resistance furnace, by several patents (1892 – 1894). The Acheson process for the production of SiC is still operated today with some improvements in detail (see Section 3.3).

An important development in the production of SiC in resistance furnaces took place in Germany in 1972 – 1974. Elektroschmelzwerk Kempten (ESK) developed a furnace in which the gases produced in the reaction are collected and used for energy production. The ESK process also made an important contribution to environmental protection (see Section 3.4).

Natural Occurrence [3]. MOISSAN found some hexagonal SiC crystals in a sample of a meteorite from the Diablo Canyon in Arizona (1905). The mineral was named moissanite after its discoverer. Later it was found that the Diablo Canyon sample was contaminated with synthetic SiC. Not until 1957 was the natural occurrence of SiC confirmed when it was discovered in Siberian kimberlite. Since then, moissanite has been found in various parts of the world, in plutonites, vulcanites, sediments, and metamor-

Figure 1. Phase diagram of a silicon – carbon system [4]

phites. It always exists as single crystals with a cross section of ca. 1 mm. Extraterrestrial occurrences of SiC are even rarer. Its existence in interstellar space has been shown by spectral measurements, and it has also been found in samples of moon rock.

2. Properties

The two-component system silicon – carbon contains the single compound silicon carbide [*409-21-2*], SiC, M_r 40.097, $\varrho = 3.21$ g/cm^3, with the composition 70.05 wt % Si, 29.95 wt % C. The Si – C bond is homopolar. Silicon carbide does not exhibit a congruent melting point. In a closed system, i.e., under equilibrium conditions at a total pressure of 0.1 MPa, SiC decomposes at 2830 ± 40 °C into carbon and a silicon-rich melt (Fig. 1) [4]. In an open system (e.g., in the Acheson furnace) decomposition begins at ca. 2300 °C whereby graphite remains behind as a pseudomorphic residue (i.e., having the shape of SiC).

Crystal Structure. Silicon carbide exists as both polymorphs and polytypes. Each C atom is surrounded tetrahedrally by four Si atoms, and each Si atom by four C atoms. These tetrahedra are arranged in planes perpendicular to the *c*-axis. Relative to one other, they can occupy the A, B, or C position of the close-packed structure. Depending on the stacking sequence, the unit cell therefore has a variable number of SiC layers in the direction of the *c*-axis. Consequently silicon carbide occurs in two modifications: cubic β-SiC and α-SiC, which includes a large

number of hexagonal and rhombohedral crystal types. The latter have been termed polytypes by several authors. RAMSDELL [5] classifies β-SiC and the various α-types by the number of SiC layers per unit cell and the crystal classification (C: cubic, H: hexagonal, R: rhombohedral). Industrial SiC contains almost exclusively β-SiC 3 C and the α-types 4 H, 6 H, and 15 R [6].

β-SiC is metastable and, in accordance with Ostwald's rule, is formed initially in SiC production. It changes into α-SiC above 1900 °C. In a nitrogen atmosphere at high pressure, β-SiC is the stable form, so that above 2000 °C α-SiC transforms to β-SiC [7]. LUNDQUIST [8] observed that the proportion of crystal types in α-SiC depends significantly on the aluminum content (Fig. 2). Pure α-SiC mainly crystallizes as 6 H. With small amounts of Al, 15 R also occurs. Above 0.1 % Al, 4 H predominates.

Figure 2. Proportions of polytypes in technical-grade SiC as a function of Al content

Color. Pure α-SiC is colorless, while the cubic β-modification is yellow. The only other elements that can be included in the SiC crystal lattice in amounts > 1 ppm are N, Al, and B. Nitrogen gives a green color to 3 C and 6 H, and a yellow color to 4 H and 15 R. The presence of the trivalent elements boron and aluminum gives all the modifications and polytypes a blue-black color [9].

Hardness. The industrial importance of silicone carbide is mainly due to its extreme hardness of 9.5 – 9.75 on the Mohs scale. Only diamond, cubic boron nitride, and boron carbide are harder. The Knoop microhardness depends on the crystal orientation, and lies in the range of $H_{K,0.1}$ 2100 – 2900 [10]. The effects of crystal type and doping (color) are small and insignificant compared with this hardness range.

Silicon carbide is very brittle, and can therefore be crushed comparatively easily in spite of its great hardness.

Thermal and Calorific Properties. For a ceramic material, silicon carbide has an unusually high thermal conductivity: 150 kJ m^{-1} h^{-1} K^{-1} at 20 °C, and 54 kJ m^{-1} h^{-1} K^{-1} at 1400 °C [11]. α-SiC has a very low thermal coefficient of expansion of 4.7×10^{-6} K^{-1} (20 – 1400 °C), which is the reason why silicon carbide refractory products are so outstandingly resistant to thermal shock.

The specific heat capacity of SiC is 0.67 J g^{-1} K^{-1} at room temperature, and 1.27 J g^{-1} K^{-1} at 1000 °C. The standard enthalpy of formation ΔH^0_{298K} is -71.6 ± 6.3 kJ/mol, and the entropy S^0_{298K} is 16.50 ± 0.13 J mol^{-1} K^{-1} [12].

Optical Properties. α-SiC is birefringent due to its crystal structure: $n_0 = 2.649 - 2.649$, and $n_E = 2.688 - 2.693$ (Na 589 nm, 20 °C) [13]. For β-SiC, a refractive index of ca. 2.63 (Li 671 nm) has been reported [14].

Electrical Properties. Silicon carbide is a semiconductor. Doping with the trivalent elements aluminum and boron gives the SiC *p* character, while the pentavalent element nitrogen produces *n* character when incorporated into the SiC crystal lattice. The resistivity lies between 0.1 $\Omega \cdot$ cm and 10^{12} $\Omega \cdot$ cm, depending on the concentration of lattice defects [15].

Whereas compact, homogeneous silicon carbide obeys Ohm's Law, aggregates of SiC grains show nonlinear current – voltage behavior. At low applied voltages they behave as insulators, but when the applied voltage is increased above a certain value, the current increases exponentially. Thus, the points of contact between the grains cause the electrical resistance to be voltage dependent [15, 16].

Chemical Properties. In addition to its hardness, an important property of silicon carbide is

its chemical resistance. It is resistant to organic solvents, alkalies, acids, salt solutions, and even aqua regia and fuming nitric acid.

The behavior of silicon carbide towards oxygen and oxygen- containing gases is of industrial importance. The oxidation of pure SiC begins at ca. 600 °C, forming a coating of SiO_2 on the surface of the SiC that prevents further oxidation [17].

$$SiC + 2\,O_2 \longrightarrow SiO_2 + CO_2 \quad (1)$$

The reaction rate varies with time according to a parabolic law [18]. The kinetics are determined by the diffusion of oxygen through the SiO_2 layer. The effect of temperature on the reaction obeys the Arrhenius Law.

The "active" oxidation of SiC is distinguished from the "passive" oxidation reaction described above.

$$SiC + O_2 \longrightarrow SiO + CO \quad (2)$$

Active oxidation takes place under conditions of oxygen deficiency above 1000 °C, and leads to decomposition of the SiC and formation of SiO [17, 19].

Thus, silicon carbide is attacked and decomposed by an oxidizing agent if the protective layer of SiO_2 is removed, thereby enabling the reaction to proceed unhindered. SiC is decomposed in this way by fused alkalies such as $Na_2CO_3 + Na_2O_2$ or $Na_2CO_3 + KNO_3$. Fused lead borate in the presence of oxygen causes complete decomposition of SiC. Pb_3O_4 or a mixture of $K_2Cr_2O_7$ with $PbCrO_4$ reacts very vigorously on heating with silicon carbide.

A mixture of hydrofluoric acid, nitric acid, and sulfuric acid slowly attacks silicon carbide, β-SiC being somewhat more reactive than α-SiC [20]. However, complete dissolution only takes place if the SiC is very finely divided, under pressure, and at a high temperature (e.g., 250 °C for 16 h).

Chlorine reacts with SiC above 800 °C, forming silicon tetrachloride and carbon.

Silicon carbide behaves towards molten metals in various ways. It is not attacked by molten zinc or zinc vapor [21]. Molten aluminum attacks SiC slowly, forming Al_4C_3 and Si, but as the Si content increases, the reaction eventually ceases because an equilibrium is established [22]. Molten iron dissolves SiC, forming iron carbide and iron silicide.

3. Production

3.1. Reaction Mechanism

Silicon carbide is produced industrially from silicon dioxide and carbon, which react according to the overall equation:

$$SiO_2 + 3\,C \longrightarrow SiC + 2\,CO \quad (3)$$

The reaction is strongly endothermic with $\Delta H_{298K} = +618.5$ kJ/mol [12], corresponding to 4.28 kWh/kg α-SiC.

The reaction in fact takes place in several stages. The initiation reaction

$$SiO_2 + C \longrightarrow SiO + CO \quad (4)$$

is thermodynamically possible above ca. 1700 °C and in fact begins when the SiO_2 melts. The next stages are

$$SiO + C \longrightarrow Si + CO \quad (5)$$
$$Si + C \longrightarrow SiC \quad (6)$$

The SiC is formed as an incrustation on the carbon grains, preventing further formation of SiC, and ultimately causing the reaction to cease. The SiC then reacts further

$$SiC + 2\,SiO_2 \longrightarrow 3\,SiO + CO \quad (7)$$
$$SiC + SiO \rightleftharpoons 2\,Si(g) + CO \quad (8)$$

The equilibrium reaction (Eq. 8) is mainly responsible for the formation of the large SiC crystals [23].

3.2. Raw Materials

The yield and quality of silicon carbide are seriously affected by any impurities present in the raw materials. Therefore high-purity raw materials must be used.

The source of silicon is very pure, natural silica sand or ground quartz. The SiO_2 content is 99.0 – 99.9 %, preferably > 99.7 %, depending on the quality of SiC required. The usual impurities are Fe_2O_3 (0.01 – 0.05 %) and Al_2O_3 (0.02 – 0.50 %) [9].

The preferred carbon source is low-ash petroleum coke, with a typical composition: 93.7 % C_{fix}, 6.2 % volatiles, and 0.1 % ash [24]. Charcoal and anthracite are also used to produce silicon carbide, but these materials are not sufficiently pure to produce the highest quality SiC grades such as green SiC.

The raw materials should have a maximum grain size of 10 mm. The mixing ratio is precisely determined from the analysis of the raw materials, and corresponds to the stoichiometry given by Equation 3. To produce 1 t SiC, 1.5 – 1.6 t silica sand and 1 – 2 t coke or coal are required [25].

Some producers add 1 – 2 % sodium chloride to the mixture of raw materials, which is intended to remove metallic impurities by converting them to volatile chlorides. However, the effectiveness of this technique is disputed [26].

Sawdust is mixed with the raw materials to give a loosening effect. This promotes release of the carbon monoxide formed at the same time as the SiC.

3.3. The Acheson Process

The process developed by Acheson is still operated today essentially unchanged [1,27, 28]. Electrical resistance furnaces of rectangular cross section are used (Fig. 3). The electric current is fed into the furnace via graphite or carbon electrodes inserted in the end walls. The side walls are removable to facilitate discharging of the product.

The furnaces are filled with the raw material mixture by a crane. When about half of the material has been charged, the heating resistance, made of graphite, calcined pitch coke, or petroleum coke, is inserted, joining together the two electrodes in the end walls of the furnace. This so- called core is then covered with the remainder of the reaction mixture.

The electrodes are then connected to the transformer, and the current is switched on. The silicon carbide is formed around the hot core in the form of a polycrystalline, compact cylinder (the so- called roll, see Fig. 4). The surrounding reaction mixture acts as a thermal insulator. The carbon monoxide byproduct escapes through the surface of the reaction mixture and through slits in the side walls, where it burns. Because the reaction mixture is consumed during SiC formation, more reaction mixture is charged periodically to the process.

After the current is switched off, the furnace is allowed to cool for several days. Then the side walls are removed, and the excess reaction mixture is carried off. The roll of silicon carbide contains not only the original resistance core, but also graphite formed by decomposition of silicone carbide. The boundary between the graphite and the SiC is very sharply defined. The innermost SiC zone is of the highest quality, as the purest and largest crystals can form in this region. Moving outwards, i.e., with decreasing temperature, the crystal growth rate decreases, and the SiC roll becomes more and more finely crystalline. The outer zone is composed of very fine crystals of β-SiC. The SiC roll is covered with a whitish crust (siloxicon or firesand), which consists of coke grains partially converted to SiC, and compounds of silicon with oxygen and nitrogen. This is the region of the initiation reaction (Eq. 4), with which SiC formation begins.

When the SiC roll has been isolated and cooled, it is broken down piece by piece and taken for further treatment (see Section 3.5). The graphite from the core is recovered and reused.

Without exeption, several furnaces are operated in a group and associated with a single transformer. In this way, one furnace is always in operation while the others are cooling, being broken down, or being recharged.

Acheson silicon carbide furnaces can be up to 25 m long, 4 m wide, and 4 m high, consuming up to 5000 kVA, and running for ca. 130 h. The largest furnaces operate at up to 25 000 A.

The electrical energy is usually supplied as three phase a.c. Therefore, a silicon carbide production plant usually employs three groups of furnaces, so that a symmetrical load is applied to the supply network.

For optimum operation of the installed power supply, the wattless current should be as low as possible. This is achieved by suitable design and construction of the secondary circuit, and by capacitative compensation for the wattless current. An alternative to this is to operate the furnaces with d.c. [29].

Acheson silicon carbide furnaces are installed in large buildings with open roof hoods. The CO_2 and SO_2 formed by the combustion

Figure 3. Acheson furnace
a) Electrical supply; b) Electrode; c) Stationary end wall; d) Movable side wall with openings for furnace gases; e) Furnace gases; f) Reaction mixture; g) Heating resistor (core); h) Graphite from decomposition of SiC; i) Silicon carbide: coarsely crystalline inner zone; j) Silicone carbide: finely crystalline outer zone ("amorphous")

of the CO and sulfur at the top of the furnace, and other odorous components, escape through the openings in the roof. The walls of the building are provided with openings near ground level through which fresh air enters. Generally, the natural convection caused by the furnaces adequately ventilates the building, so that additional ventilation equipment is unnecessary. Most Acheson plants are not provided with waste-gas purification equipment.

A comparative review of some Acheson plants is given in [30].

3.4. The ESK Process

A major disadvantage of the Acheson process is that the byproduct CO cannot be recovered and used. Moreover, the SO_2 and dust in the waste gases cause pollution.

These disadvantages led to the development of the ESK process [31–36], which also uses a resistance-heated furnace, although the only design feature it has in common with the Acheson furnace is the horizontal heating core. The ESK furnace (Fig. 4) has no walls, and the electrodes are located in the floor. A graphite column is placed upon each electrode, and the coke–sand mixture is charged by wheel loaders until it reaches the top of the graphite columns. The heating core, which can be linear or U-shaped, is then put in position and connected to the graphite columns. The heating core is then covered with the rest of the mixture, forming a mound ca. 6 m in height. The mound is covered with a plastic sheet which traps the reaction gases evolved during operation of the furnace, causing the sheet to inflate and protecting it from the heat. The rate of gas removal is adjusted so that the pressure under the sheet remains constant.

This technique enables the byproduct CO to be collected, purified, and used. The most modern ESK furnace plant to date is in Delfzijl, in the Netherlands. It includes a desulfurization plant from which elemental sulfur can be obtained, and also includes a power station which recovers some of the energy used in the SiC production.

After the power to the furnace is switched off and the sheet pulled off, the excess reaction mixture is removed by heavy equipment. Dust formation is reduced by damping down with water.

ESK furnaces are considerably larger than Acheson furnaces, the transformers having an installed power of up to 15 MVA. The heating core can be 60 m in length when the U-shaped configuration is used.

3.5. Processing of the Crude Product

The lumps of silicon carbide obtained on dismantling the furnace are taken to a sorting area and broken down with hydraulic equipment and compressed air hammers. The finely crystalline outer zone (the so-called amorphous zone) is further size reduced (e.g., in a jaw crusher) and is

Figure 4. ESK furnace

usually returned to the furnace process by adding it to the coke – sand mixture. Alternatively, this 90 – 95 % SiC material is a valuable raw material for the production of grain refiners for the ferrous metal industry (see Section 6.3).

The coarsely crystalline, compact pieces from the inner zone of the SiC roll are sorted according to criteria such as color, structure, etc. This top-grade material forms the largest fraction of the SiC yield from a furnace charge.

The large pieces of silicon carbide are size reduced in stages using conventional size-reduction equipment such as jaw crushers, gyratory crushers, hammer mills, roll mills, ball mills, and jet mills. The choice of equipment depends on the desired size and shape of the SiC grains.

Due to the hardness of silicon carbide, some contamination of the product by abrasion of the grinding equipment cannot be avoided, whatever material of construction is used. It is therefore best to use steel, so that the abrasion products can easily be removed by magnetic separators.

For applications that require a particularly high grade of silicon carbide, such as industrial ceramics, the refractory industry, and ceramic-bound abrasives, the granular product must be washed with alkali or acid to remove adhering traces of elemental silicon, metals, metal compounds, graphite, dust, and silica.

Sieving, classification, and sedimentation processes are used to prepare various fractions with very narrow and precise grain size distributions to meet international standards for abrasive grits.

The same technique is used to obtain products for ceramics and refractory materials. These generally have a broader particle size distribution than that required for abrasives, which, however, is specified for each particular application.

Particle sizes range from ca. 5 mm down to the submicron range.

3.6. Other Production Methods

Attempts have been made to produce silicon carbide continuously from coke and sand. However, due to the relatively short reaction times that can be achieved, only agglomerates of very fine β-SiC crystals can be produced, and these are unsuitable for most applications of silicon carbide.

The manufacture of sintered SiC articles requires ultrafine SiC powder, which is generally produced by grinding commercial α-SiC in ball mills, colloid mills, or attritors to give the desired particle size of < 1 µm. An important new process is the direct manufacture of sinterable β-SiC powders from the gas phase by decomposing gaseous silicon halides in the presence of hydrocarbons in a plasma jet reactor [37]. In another CVD process, the starting materials are organosilicon compounds [38]. Nucleation must take place in the gas phase for powders to be formed.

Another method of producing a sinterable β-SiC powder is the carbothermic reduction of finely divided SiO_2 [39].

The thermal decomposition of rice husks gives a very finely divided form of β-SiC [40]. The yield is ca. 10 % based on the total raw material used. Some of the product has the form of whiskers.

The formation of silicon carbide from the elements is used in the manufacture of ceramic components (see Section 6.6). In one process, carbon or carbon-bonded silicon carbide moldings are infiltrated with molten silicon and converted into SiC (SiSiC). In another process, the batch contains elemental carbon and silicon, which are converted to SiC by subsequent heat treatment. The product is known as reaction-bonded silicon carbide (RBSiC).

Carbosilane resins have been proposed as precursors which yield SiC on pyrolysis. The high cost of this process, however, prevents its application on a wider scale.

Fibrous SiC (whiskers) is obtained in various CVD processes in which SiC is precipitated in the presence of catalysts. The preferential one-dimensional growth of these crystals proceeds by a vapor – liquid – solid (VLS) mechanism [3].

4. Quality Control

The SiC content of silicon carbide products is now usually determined by measuring the carbon content. The total carbon content is determined by combustion of the sample in a stream of oxygen at 1050 °C in the presence of lead borate. The CO_2 produced is absorbed in $Ba(ClO_4)_2$ solution and determined by coulometry [41,42]. An alternative technique is to oxidize the SiC with oxygen in a high-frequency induction furnace containing a flux metal, and to detect the CO_2 produced by IR absorption.

Free carbon can be directly determined coulometrically by combustion at 850 °C without any additives, provided that the SiC itself is not appreciably oxidized. If the SiC samples are very finely divided, i.e., have large specific surfaces, and if long heating times are required due to high free carbon contents, this method cannot be used. In such cases, the weight change on combustion is measured, and the decrease in total carbon content is determined. This enables the effect of the unavoidable oxidation of the SiC to be eliminated, and the free carbon content to be calculated [41,42].

Analyzers with IR detection are also suitable for the direct determination of free carbon provided that they allow precise temperature control during combustion of the free carbon.

The SiC content is calculated from the difference between total and free carbon.

The free silicon content is determined by measuring the volume of hydrogen produced on treatment with sodium hydroxide solution. Alternatively, metallic silver is precipitated from a silver fluoride solution, dissolved in nitric acid, and determined by a standard method [41,42]. In the chemical analysis of SiC abrasive grits, emphasis is placed on the determination of accompanying materials such as carbon, silicon, silicon dioxide, and metallic oxides. The SiC content (plus the free carbon) is found by weighing the residue after treatment with a mixture of hydrofluoric, nitric, and sulfuric acids [42]. For special grades of SiC for refractory and metallurgical applications, volatile components can interfere with the SiC determination. In this case, the sample must first be annealed under argon [43].

Besides chemical analysis, physical properties such as particle size, particle size distribution, and bulk density are also important.

The particle size distribution of coarse abrasive materials (5 mm – 50 µm) is determined by sieving. For particle sizes less than 50 µm, sedimentation and laser diffraction methods are used.

Both the particle size distributions and the methods for their determination are standardized. The standards for bonded abrasive applications [44] differ from those for coated abrasives [45]. The bulk density depends both on the particle size distribution and on the particle shape. It is measured by weighing a known volume of SiC grains [46]. The packed density is often determined instead of the bulk density [47].

5. Toxicology and Occupational Health

Silicon carbide is nontoxic, and is therefore a nonhazardous material as defined by GefStoffV.

For fiber-free, finely divided SiC, the MAK value is 4 mg/m^3 [48]. If the MAK is exceeded, a dust mask with a P 1 filter (for inert dusts) must be worn. However, since these SiC dusts are not fibrogenic [49], so that there is no MAK value.

Conclusive experimental studies on the effects of respirable fibrous SiC dusts (whiskers) are not yet available [50].

Silicon carbide can be disposed of together with ordinary domestic refuse provided that local regulations are observed. There is no legal requirement for documentation.

6. Uses

6.1. Abrasives (see also → Abrasives)

The extreme hardness of silicon carbide led to its use as an abrasive immediately after its discovery. Silicon carbide is used directly as a loose-grain abrasive for cutting with wiresaws and for lapping. It is also used in bonded form. The latter use can be divided into two groups:

1) Bonded abrasives include grinding wheels, whetstones, hones, abrasive cutting-off wheels, and monofiles. The SiC grains can be bonded with plastics or ceramics.
2) Coated abrasives include abrasive paper and cloth in sheet or band form. They are produced by strewing the SiC grains onto a substrate coated with glue or bonding resin and then covering with a second layer of bonding agent [51].

6.2. Refractories

High resistance to oxidation, high thermal conductivity, and low coefficient of thermal expanison make silicon carbide ideal for use in refractory raw materials and finished products. Its hardness and abrasion resistance are additional advantages, so that the range of applications in the field of refractory materials is wide [13]. The following examples are therefore by no means complete.

The commonest products are clay-bonded moldings and monolithics with SiC contents of 40 – 90 %. These are used for blast furnace linings and runners; muffle plates and chambers in industrial furnaces; column trays for zinc distillation; boiler furnace linings in thermal power stations; incinerators for domestic refuse; and for kiln furniture used in the manufacture of porcelain and earthenware products.

Quality standards continually increase (especially for kiln furniture), with regard to durability, strength, and weight saving, so that classical clay bonding is being increasingly replaced by the use of synthetic oxides or Si_2ON_2, Si_3N_4, and SiC.

In the case of nitride or oxynitride bonding, the starting material is a mixture of SiC with a few percent elemental silicon. This is shaped by pressing or casting, and then calcined in the presence of precisely controlled amounts of nitrogen or air.

Kiln furniture made of recrystallized SiC (RSiC) is manufactured from a mixture of 70 % silicon carbide with a grain size of ca. 100 µm (the structural particles) and 30 % of a very fine grade of SiC having a particle size distribution ranging from 10 µm to the submicron range (the bonding particles). The mixture is formed by slip casting. The green castings are fired at 2100 – 2500 °C under a protective gas (e.g., argon). No shrinkage takes place. The coarse particles of SiC grow at the expense of the small particles. This takes place mainly at the contact angles between the structural particles, resulting in high strengths, which are maintained even at working temperature (ca. 1500 °C in air) [52]. The finished RSiC articles, which are used as supporting plates, saggars, and transporting rolls for fast-firing kilns, and as supporting beams for firing suspended articles, have a wall thickness ca. 50 % lower than those made of oxide-bonded silicon carbide [53].

A similar development has taken place in the field of silicon carbide blast furnace linings. Here, silicon carbide bricks are bonded with Si_3N_4 and SiC, and sometimes other nitrogen-containing bonding agents such as Si_3N_4/sialon (→ High-Temperature Materials, Chap. 9.3.8.) and Si_2ON_2. Pure SiC bricks are also used. Bricks bonded with α-SiC (firing temperature > 2000 °C) have improved durability compared with reaction-bonded SiC (RBSiC), in which the bonding phase is β-SiC due to the lower firing temperature of 1400 – 1500 °C. When selecting a construction material, the best compromise

must be found with respect to its resistance to alkali attack, oxidation, thermal shock, and abrasion [54, 55].

Silicon carbide is also used in combination with carbon or graphite for refractory applications, e.g., in the graphite- clay bricks used in nonferrous metallurgy. They contain up to 35 % SiC to improve the refractoriness under load.

The use of SiC in the manufacture of filters for casting metals has increased. These filters are fitted to the mold ingate and give a considerable improvement in casting quality. Filters made of SiC are used in gray iron foundries [56]. To produce the filter body, a molding made of open-cell polyurethane foam is saturated with a slurry of SiC, Al_2O_3, and a high-temperature binder such as aluminum dihydrogenphosphate. After drying, the plastic is burnt off, and the ceramic is fired [57].

Structural ceramic materials that are also refractory components include heat exchangers, burner nozzles, etc., made of SiC. The most commonly used varieties of this material are recrystallized silicon carbide (RSiC) and silicon-infiltrated silicon carbide (SiSiC).

6.3. Metallurgy

The iron and steel industries consume large quantities of silicon carbide for deoxidizing high-alloy steels and for adding silicon and carbon to cast iron [58]. The SiC used is of the quality found in the outer zone of the SiC roll (see Section 3.3), as this material dissolves more readily in the molten ferrous metal owing to its fine crystalline structure. In cast iron production, the SiC is added to the feed of the cupola in the form of cement-bonded briquettes. Silicon carbide is used in granular form for deoxidizing steel in the ladle [59].

6.4. Electrical Technology

The semiconducting properties of silicon carbide have long been utilized in resistance heating elements. Metallic heating elements cannot be used in laboratory and industrial furnaces that operate at up to 1500 °C. Instead, elements made of pure SiC in the form of rods, tubes, or helical shapes are used. These are produced from SiC grains bonded by silicon infiltration or by the reaction bonding method (see Section 3.6).

Voltage-dependent resistors (varistors) consist of SiC particles bonded with ceramic or polymer binders (see Section 3.6). They are produced in the form of discs or blocks, or in cuboid or ring shapes, and are the active elements in overvoltage protection equipment such as lightning protection devices and surge arresters. Not only the electrical properties of the silicon carbide are exploited, but also its resistance to chemical attack, which gives the SiC conductors outstanding stability. Silicon carbide allows arresters to be produced that combine low protection levels with good stability to prolonged overvoltage, such as can occur in earth faults in electrical supply systems with an isolated or resonant earthed neutral [60].

High-voltage cables and generators are protected from local discharges by using SiC powder as a filler in the insulating coating (corona shielding).

When used in floor coverings, silicon carbide gives antislip and antiabrasion properties, and eliminates static electricity.

6.5. Electronics

Silicon carbide is an outstanding material for the construction of electronic equipment such as rectifying diodes for high temperatures and/or high energy densities. Blue light-emitting diodes can be produced from SiC single crystals (→ Electroluminescent Materials and Devices, Chap. 4.2.) [61]. However, it is not yet possible to mass produce these economically.

Hydrogenated amorphous SiC compounds of the type $Si_{1-x}C_x$: H, which can be produced as thin films by glow discharge deposition onto silicon or other substrates from mixtures of SiH_4, C_2H_4, and H_2, seem to have a range of potential applications, e.g., in rectifiers [62], light-dependent resistors [63], electrophotographic receptors [64], and light-emitting diodes [65].

6.6. Structural Ceramics

Pumps used in the chemical industry for feeding and metering strongly corrosive and abrasive materials are provided with slide-ring seals

made of sintered SiC. For similar requirements involving radial loads, sliding bearings and shaft housings are manufactured from sintered silicon carbide. The same material is used to produce ball valves and other parts for metering pumps and fittings [66]. The starting material for the manufacture of these structural ceramic components is submicron SiC powder (see Section 3.6).

For the production of sintered silicon carbide moldings, a wide range of sophisticated production steps are available, depending on the properties required of the end product. The SiC powder is first mixed with sintering aids and temporary binders, and is conditioned preparatory to the forming stage. The latter is carried out by slip casting, spray casting, or compression molding. A complex heat treatment process is often included at this stage to remove the intermediate binder before the workpiece is sintered. This can be pressureless (SSiC), under unilateral pressure (hot pressing, HPSiC), or under isostatic pressure (hot isostatic pressing, HIPSiC) [67].

7. Economic Aspects

In 1995, the world capacity for silicon carbide manufacture was ca. 750 000 t/a. Of this, 165 000 t/a was from Western Europe, 145 000 t/a from Eastern Europe, 178 000 t/a from North and South America, and 266 000 t/a from the Far East.

1. Introduction

A number of inorganic compounds of silicon have gone through a remarkable development in the past years, prompted chiefly by the electronics industry and efforts of environmental protection. A tremendous growth of knowledge in physics and chemistry, as well as technical applications, has taken place around certain hydrides, halides, and oxides of silicon. Progress in solid state physics, the material sciences, and an increase in unwanted byproduct formation in the course of production of large-scale silicon compounds have necessitated that one look anew at process engineering. Energy consideration is of direct bearing in this technology since most processes in technical silicon chemistry require high temperature.

Environmental protection and elimination of safety hazards during production and handling of the above silicon products has been the concern of all ever since these compounds became large-scale technical products. The moisture sensitivity of the halides, the oxygen sensitivity of the hydrides, and pyrophoric properties of some of the distillation residues from reaction steps involving elementary silicon or silicides have caused waste problems and particular emphasis on process safety. Greater flexibility of chemical transformation within at least partly recycling procedures have both decreased waste and enhanced safety. Making use of byproducts has been extended to comprise substances of the system C – Si – O – Hal, its phases and transformations. Alongside product making, byproduct formation, its investigation, suppression, or transformation into useful silicon derivatives has been to some degree due to efforts of environment protection.

With respect to use, many new applications were found for special inorganic silicon compounds, optical fibers and solar cells being example for both surface as well as bulk properties.

Surface treatments, not necessarily confined to protective coatings but including migration beneath the surface, are carried out to increase hardness, thermal stability, to influence cohesion and adhesion, to resist oxidation, erosion, corrosion, and to enhance reflexion, etc. Interfaces and multilayer cermets and plastics need silicon in various bonding states as intermediates during production or permanently in a final product.

2. Silicon Hydrides

Silicon hydrides are sensitive to hydrolysis and oxidation; volatile higher silanes are spontaneously flammable [1–3]. The first five members of the homologous series Si_nH_{2n+2} are known in the pure state (see Table 1).

All silanes are decomposed in reactions of the type:

The thermal decomposition of monosilane takes place as follows:

Higher silanes decompose at lower temperature.

High-purity silicon can be produced in this way from pure silanes. Organosilicon compounds can be obtained by addition of silanes to unsaturated organic compounds.

2.1. Monosilane

Monosilane, SiH_4, is formed by the hydrolysis of magnesium silicide (Mg_2Si) with 10 % hydrochloric acid at 50 °C. It is, however, accompanied by higher homologues which must be removed by high-vacuum fractionation [4,5]. However, if magnesium silicide is hydrolyzed with ammonium chloride in anhydrous ammonia under its own vapor pressure at room temperature, SiH_4 is obtained exclusively [6]. Ammonium bromide has also been used [7]. The ammonia is condensed out as far as possible, and any remaining traces are removed by washing the silane with dilute nitric acid.

Silane can readily be prepared from silicon halides and metal hydrides. The most convenient laboratory method is the reaction of $SiCl_4$ with lithium aluminum hydride in diethyl ether [8] or THF [9].

$$SiCl_4 + LiAlH_4 \longrightarrow SiH_4 + LiCl + AlCl_3$$

The hydrogenation can also be performed with alkali metal hydride/aluminum alkoxide or alkali metal hydride/boron triethyl in paraffin oil [10], or by alkali metal aluminum hydride/calcium aluminum hydride in other organic solvents [11,12].

The alkali or alkaline-earth metal hydrides can be formed in situ by passing silicon tetrachloride and hydrogen into an electrolyzed melt of the metal halide [13].

In a two-step process, in which the rate of silane formation is adjusted by means of the temperature difference between the two stages, silicon halides other than the tetrafluoride are first reacted with excess alkali metal hydride or alkali metal aluminum hydride, followed by degassing and then contacting the solid reaction product with excess silicon halide [14]. Monosilane is obtained in low yield but with sufficient purity to be used in the manufacture of semiconductors with toluene as a solvent instead of ethers [15].

Benzyltriethylammonium chloride or other quaternary ammonium salts are used as catalysts in concentrations up to 25 mol %. High yields of monosilane are obtained from the reaction of silicon halides with a mixture of aluminum products containing dialkyl aluminum hydrides, trialkylaluminum, ethylaluminum chloride, and aluminum powder in liquid paraffin at 40 °C.

Catalytic disproportionation of chlorosilane mixtures originating from various sources in the silicon industry provides a route to monosilane for the manufacture of polycrystalline solar silicon. For a mixture of trichloro- and dichlorosilane, copper [16], a mixture of silica and alumina at 300 °C [17], and quaternary ammonium groups bonded to carbon in an ion-exchange resin have been reported as catalysts for the main reactionleading to monosilane [18].

The catalytic conversion of intermediate dichlorosilane can also be accomplished by alkyl or aryl nitriles on carbon carriers at 50 °C [19]. Boron catalysts, however, enhance the formation of dichlorosilane in chlorosilane mixtures obtained by high-pressure plasma hydrogenation of tetrachlorosilane [20]:

Table 1. Silanes Si_nH_{2n+2}

	M_r	*mp*, °C	*bp*, °C	d_4^{20}
SiH_4	32.12	−185	−112	0.68
Si_2H_6	62.23	−130	− 14.5	0.69
Si_3H_8	92.33	−117	− 53	0.72
Si_4H_{10}	122.44	− 91	−108	0.79

$$SiCl_4 + H_2 \longrightarrow HSiCl_3 + H_2SiCl_2$$

In-process purification is achieved by contacting part of the monosilane produced with the starting mixture of chlorosilanes, which contains the impurities as chlorides, chiefly those of arsenic, phosphorus, and boron. This procedure converts the contaminants into their more volatile hydrides, which are removed with the off-gas [18].

Properties and physical data of monosilane, particularly with regard to obtaining high-purity silicon by chemical vapor deposition, are compiled in [21].

2.2. Disilane

Increasing amounts of hexachlorodisilane are being produced as a byproduct of the chlorosilane industry. Since it is of no immediate use, it is subjected to hydrogenation or disproportionation to convert it to useful derivatives, mainly tetra- or trichlorosilane. When the production of amorphous silicon from disilane became commercially viable, the hydrogenation of hexachlorosilane became a feasible alternative to disproportionation. The production of disilane resembles that of monosilane, the reducing agents being metal hydrides, mainly lithium aluminum hydride. The use of di-*n*-butyl ether as a solvent is reported to give a smooth reaction at 35 °C [22]. Addition of lithium hydride increases the yield molar ratios $LiH : LiAlH_4$ of 0.8, 2.0, 12.0, 20.0, and 40.0 resulted in yields of 83, 88, 90, 89, and 70 %, respectively. Lithium hydride can be used as the sole reducing agent if aluminum bromide or chloride is added to the ether solvent [23]. Lithium aluminum hydride in refluxing diethyl or diisopropyl ether gave disilane in 88 % yield [24].

2.3. Purification

Removal of boron compounds from silanes that are to be used for the production of high-purity silicon is very important. When SiH_4 is produced from alkali metal hydrides [12], it is recommended that water should be added to hydrolyze boron hydrides under the alkaline reaction conditions. Water vapor is added during distillation for the same reason [25]. Boron compounds can be removed from SiH_4 by adsorption from the gas phase onto activated carbon or silica carriers loaded with compounds that form complexes with boron compounds ($AlCl_3$, $FeCl_3$, C_2H_5CN, NH_2CN, PCl_3) [26].

If alkali metal hydrides MH are reacted in organic solvents, it is often unnecessary to include a special stage for removing boron compounds from the silicon compounds, as the former react to form boranate complexes under the following conditions:

$$SiCl_4 + 2\,BCl_3 + 10\,MH \longrightarrow 10\,MCl + SiH_4 + B_2H_6$$

$$B_2H_6 + 2\,MH \longrightarrow 2\,MBH_4$$

A systematic study has been carried out on the liquid – vapor distribution coefficients of volatile trace impurities in the hydrides of boron, silicon, phosphorus, arsenic, sulfur, and selenium. Experimental and calculated data are reported for the temperature range between the boiling point and critical temperature. Linear regression coefficients for the temperature dependence of the impurity distribution coefficients are included [27].

2.4. Uses

Direct use of silicon hydrides involves their decomposition on surfaces, leading to deposition of elemental silicon or silicon compounds.

Polycrystalline films of elemental silicon of controllable grain size are deposited on glass or silica-coated surfaces by heating them to 450–800 °C in an atmosphere consisting of monosilane and tetrabromo- or tetraiodosilane [28]. Chemical vapor deposition is generally followed by annealing and recrystallization with an energy beam. This is used to deposit silicon on insulator surfaces [29]. Amorphous silicon photoconducting layers on electrophotographic plates are made by using a plasma for silane decomposition and silicon deposition [30]. Liquid crystal displays, based on thin film transistors, for screens in monitoring devices, are made from amorphous silicon which is produced on alkali-free glass surfaces in situ by an electric discharge in an atmosphere of monosilane at reduced pressure. Residual bonds are saturated by hydrogen atoms to avoid diminishing the semiconductor effect [31]. On the surfaces of transition metals, cleaned by sputtering in an argon atmosphere, monosilane and the higher silicon hydrides can be thermally decomposed at ca. 300 °C to form metal silicides [32]. Exposure to air leads to the formation of silicon oxides.

2.5. Safety Measures

Silicon hydrides are combustible; the lower members are spontaneously flammable. Particular attention has been given to the system monosilane – oxygen and its explosibility [33]. Oxygen-rich mixtures (>70 % O_2) give water and silicon dioxide as combustion products. As the mixtures become richer in monosilane, hydrogen replaces water as a combustion product. For monosilane-rich mixtures (>70 % SiH_4) the products are hydrogen, silicon, and silicon oxides. The explosion of monosilane-rich mixtures is primarily a thermal explosion of monosilane itself.

Hazardous waste gases containing silicon hydrides and halides are passed through columns containing pelletized oxidants to remove the silicon compounds. The oxidants are made by treating a mixture of copper and zinc nitrate with sodium carbonate [34].

2.6. Photochemistry

Irradiation of silanes and silyl compounds leads to fragments, namely the silylene (: SiH_2) intermediate. Silane mixtures with boron trichloride [35] and hydrogen chloride [36] have been investigated with infrared laser techniques.

Monosilane and boron trichloride react along two pathways, one being hydrogenation of boron compounds, leading to boron dichloride, diborane, and trichlorosilane. In a side reaction, decomposition of silane takes place, forming hydrogen and amorphous silicon. Carrying out this procedure with methane instead of silane leads to a pyrolysis of methane, the released hydrogen partly converting the boron trichloride to hydrides.

In the presence of hydrogen chloride, the primary reaction seems to be the formation of intermediate silylene which in turn reacts with silane and hydrogen chloride. Simultaneous formation of chlorosilanes also occurs. The activation energy for the insertion of silylene into hydrogen chloride was determined to be <1.3 kcal/mol. In general, silylene insertions are considered in the context of a triplet state, and symmetry allows insertions to proceed without excitation energy when the antibonding orbital, relating to the bond into which the insertion occurs, is symmetrical with respect to the reaction coordinate [37].

3. Silicon Halides

Silicon halides (see Table 2) are mostly colorless liquids that fume in air, are readily hydrolyzed, and consequently have an irritating effect on the mucous membranes. Silicon hydridohalides with a high hydrogen content are spontaneously flammable. All 18 mixed silicon halides with the composition $SiHal^1{}_nHal^2{}_m$ $(n+m=4)$ are known.

3.1. Trichlorosilane

Trichlorosilane, $HSiCl_3$, M_r 135.4, *mp* −134 °C, *bp* 36.5 °C (Table 2) is the most important silicon hydridohalide. The vapor is highly flammable; mixtures with oxygen or air explode violently on ignition or on contact with a hot surface. It is decomposed by water with the evolution of hydrogen.

Table 2. Melting and boiling points of halogenosilanes

	M_r	*mp*, °C	*bp*, °C
SiH_3F	69.12		−98.6

[a] At 1753 mbar triple point.

3.1.1. Preparation from Elemental Silicon

Trichlorosilane was first prepared by F. WÖHLER, who used the same method as that now used for laboratory and industrial scale production [38]:

$$Si + n\,HCl \longrightarrow HSiCl_3 + SiCl_4$$

A mixture of chlorinated silanes is produced when a mixture of hydrogen chloride and hydrogen at ca. 250 – 400 °C is passed over high-silicon (ca. 97 % Si) ferrosilicon or silicon mixed with aluminum, nickel, or copper(I) chloride [39]. The process is sometimes carried out in a turbulent [40–42] or nonturbulent fluidized bed [43, 44].

Due to the growing demand for pure precursors for high-purity silicon, process improvements have been made continuously to raise the yield of trichlorosilane and to lower energy consumption as the chief cost cutting measures in production. The fluidized-bed reactor [45–54] has become the predominant process base for the manufacture of trichlorosilane from metallurgical-grade silicon or other silicon solids. Additional feed gases, both inert (e.g., nitrogen, argon, and helium) or reactive (e.g., chlorine) have been used [45, 46]; feeding hydrogen chloride in pulses is reported to give a higher yield [47]. Tetrachlorosilane added to the feed gas serves as a carrier and fluidizing agent when silicon residues are utilized as a source of silicon [48]. These residues can originate from the direct synthesis of organochlorosilanes (→Silicon Compounds, Organic, Chap. 2.1.). Higher temperature in the fluidized bed followed by rapid quenching are reported to increase yield 1.8-fold. Quenching is effected by spraying the top of the bed with tetrachlorosilane at 20 °C such that the reaction gases leaving the reactor are cooled to 400 °C in less than one second [50].

Extremely fine particles of silicon (50 – 800 µm), obtained by atomizing molten elemental silicon in a nitrogen atmosphere, are claimed to give a high yield of trichlorosilane [51]. A screw conveyor has also been used for producing trichlorosilane from ferrosilicon [55]. Depending on the cooling rate the tetrachlorosilane to trichlorosilane ratio can be adjusted between 4 : 1 to 0.2 : 5.

In a two-step [56] process silicon is first reacted with tetrachlorosilane at 1100 – 1300 °C and the resulting product is treated with hydrogen chloride. The conversion of tetrachlorosilane to trichlorosilane is 50 – 60 %.

Adding tetrachlorosilane to the hydrogen chloride prior to contact with powdered silicon is claimed to enable complete conversion to trichlorosilane [57].

Silicon powder with 2 % copper [58] or 6 % copper [59], has been used at 350 – 600 °C. The yield of trichlorosilane was 7 – 27 mol % for 2 % Cu, and 80 – 90 mol % for 6 % Cu. Much lower temperatures (down to 260 °C) were possible when antimony pentachloride was used as a co-

catalyst with copper; the trichlorosilane yield was 21 % [60].

Silicon residues from direct synthesis of organochlorosilanes can also be reacted with hydrogen chloride to give trichlorosilane [61].

3.1.2. Preparation from Tetrachlorosilane

Tetrachlorosilane, up to now used as a starting material for silica fillers, quartz, and special glasses, has become an important precursor for trichlorosilane. The basic reaction is

$$1.5\,SiCl_4 + H_2 + 0.5\,Si \rightarrow 2\,HSiCl_3 \quad (1)$$

Although use of a graphite heating element at 1100 – 1400 °C has been reported [62], most processes are operated between 800 and 1400 °C. The residence time is critical and is adjusted by quenching or by using a two-step process. The residence time of the feed should be <2.5 s [63], and quenching carried out below 600 °C within <1 s [64]. A feed stream of tetrachlorosilane – hydrogen mixture with a molar ratio of 1 : 2 in the absence of silicon at 1100, 1200, and 1500 °C, gave trichlorosilane in 27, 31, and 35 %, respectively.

In two-stage processes the reaction with silicon is carried out at lower temperature in the second-stage reactor.

Typical temperatures are 500 – 700 °C for the first stage, and 300 – 350 °C for the second [65]. The yield of trichlorosilane can be doubled by adding hydrogen chloride to the gas from the first reactor prior to entering the second [66]. A reaction mixture obtained by passing tetrachlorosilane and hydrogen through a reactor at 1050 – 1250 °C is then cooled to 250 – 350 °C and reacted with silicon in a second reactor [67], giving a product containing 38 % trichlorosilane and 61 % tetrachlorosilane. It is also possible to react the intermediate dichlorosilylene with hydrogen in a separate reaction chamber [68].

Single-step processes are mostly carried out in fluidized-bed reactors [69, 70] with quenching of the gaseous reaction products. For furnaces operating at ambient pressure, preheating the reactant gases [71], and removing surface oxide coatings from the silicon powder with aqueous acid or alkaline hydrogen fluoride solution raises the trichlorosilane yield to 70 % [72]. Pretreatment of silicon can also be carried out with gaseous hydrogen chloride [73]. While particle size of the silicon and its distribution seems to have little influence on the reaction [74], it is strongly affected by catalysts. Copper, the main catalyst, is added as such to the silicon [75–81]. The reaction kinetics have been studied in the presence of copper chloride [82]. The hydrogenation of tetrachlorosilane has an activation energy of 20 – 25 kcal/mol which is lowered to 10 – 15 kcal/mol by the catalyst; conversion and throughput are improved.

Copper has also been used with cocatalysts such as metal oxides [83] and metal halides. Aluminum halides give trichlorosilane yields of 20 – 30 mol % [84–86]; iron and vanadium halides give comparable yields [87–89].

Using nickel salts as cocatalysts [90, 91] between 500 and 600 °C gave trichlorosilane yields of 36 % whereas powdered nickel alone gave 27 % [92]. Antimony chloride in a pressure reactor gave 21 % [93].

Platinum compounds have also been used [94, 95]. Silicon with addition of 10^{-3} mol % platinum black [96] catalyzes tetrachlorosilane conversion at 550 °C to give an 80 % yield of trichlorosilane. At the same temperature, platinum on carbon gives a mere 5 % yield [97]. Carbon as the sole catalyst has also been reported in a two-step process [98], in a fluidized-bed reactor [99], and in a packed-bed reaction chamber [100], the latter two giving trichlorosilane yields of 20 vol % and 11 mol %, respectively.

The conversion of tetrachlorosilane to trichlorosilane has also been effected electrolytically [101] with 1,2-dimethoxyethane as a solvent, hydroquinone as hydrogen donor, and tetrabutylammonium perchlorate as supporting electrolyte.

3.1.3. Purification

Extreme purification of trichlorosilane is necessary if it is to be used for production of high-purity silicon for semiconductors or photoconductors. This is mainly to remove impurities such as chlorides of calcium, aluminum, titanium, copper, magnesium, iron, boron, and phosphorus, which would remain in the silicon formed by hydrogen reduction. The trichlorosilane is treated with complexing agents

such as thioglycolic acid, β-naphthylamine, and salts of ethylenediaminetetraacetic acid [102]. An extremely pure product is obtained by extraction with CH_3CN [103]. Other methods include adsorption of the impurities on columns of activated silica [104], activated carbon, ion exchangers [105, 106], titanium sponge [107], or by treatment with acetals [108] or salt hydrates, which cause partial hydrolysis of the impurities [109–111]. The purification of trichlorosilane [112, 113], the development of purity criteria, and industrial control of purity [114] are well developed subjects.

The ultimate aim in trichlorosilane purification is the elimination of trace amounts of boron and phosphorus. Both elements are retained in chemical processing in sufficient amounts to impede or even prohibit certain uses in electronics. Boron impurities are first converted from volatile halides or hydrides to nonvolatile acids or oxides, for example, by passing moist nitrogen into the boilers of a multistage distillation [115]. The addition of 0.1 – 1.0 g/t of trichlorosilane decreased the boron content from 1.6 ppm to 0.2 ppb. A similar procedure [116] gave 12 ppb residual boron in a one-step distillation. The addition of silica with at least 0.25 wt % of total hydroxyl groups is also claimed to effect partial hydrolysis [117].

Phosphorus, the other chief contaminant of silicon compounds, is present in chlorosilanes as phosphorous trichloride. During their distillation, it is trapped in the high-boiling residue by complex formation with molybdenum oxychloride and covalent nickel compounds. The phosphorus-metal complexes are thermally stable. Residual phosphorus contents of chlorosilanes distilled were below the analytical detection limit [118, 119]. Manganese dioxide is also reported as a purification agent. It forms phosphorus oxychloride which has a much higher boiling point than phosphorus trichloride and hence remains in the distillation residues [120]. Boron and phosphorus impurities in trichloro- or dichlorosilane can be oxidized with oxygen to give less volatile compounds [121]. Polycrystalline silicon prepared from purified chlorosilanes had residual impurities of 0.1 ppb boron and 0.18 ppb phosphorus.

3.1.4. Waste Disposal

The in-plant, partly on-line conversion of waste from chlorosilane manufacture and use has two chief sources: distillation residues and off-gases which are both hazardous materials. To provide safety, environment protection, and an economic conversion of material that can be used elsewhere or safely deposited, several procedures have been adopted. Distillation sludge is evaporated in the presence of metal chloride slurries giving chlorosilanes [122] and then hydrolyzed with steam in azeotropic hydrogen chloride which continuously gives additional hydrogen chloride [123].

3.1.5. Uses

The purity of trichlorosilane greatly influences its end use. High purity silicon is produced by the pyrolysis of trichlorosilane in the presence of hydrogen [124, 125], for which a large number of techniques have been used, e.g., pyrolysis in a fluidized bed [126], pyrolysis in or over molten silicon [127–129], and epitaxial growth on silicon [130–132] or graphite [133]. Other processes reported include the production of polycrystalline silicon by the pyrolysis of trichlorosilane [134–137], the production of amorphous silicon coatings by CVD [138], and the production of solar silicon [139, 140]. A reactor made of silicon has been described for the pyrolytic process [141].

In fluidized-bed reactors caking of silicon on the inner wall is prevented by starting with a bed of polycrystalline silicon of grain size 700 – 3000 µm, fluidized by a mixture of trichlorosilane and hydrogen [142]. The polycrystalline silicon granules are continuously removed from the reactor.

Other important uses for trichlorosilane include the manufacture of very finely divided ("micronized") silica for use as a filler [143], the manufacture of silicon nitride ceramics, sometimes together with metal nitrides [144], the surface treatment of boron and borides [145], the production of free-flowing granulated fertilizers [146], and in screen printing [147].

3.2. Tetrachlorosilane

Silicon tetrachloride, $SiCl_4$, M_r 169.9, *mp* −69.4 °C, *bp* 57.3 °C, T_c 234.0, p_c 37.5 bar, V_c 326.3 cm g^{-1} mol^{-1}, is a clear, colorless liquid that fumes strongly in air and hydrolyzes rapidly in water, producing SiO_2 gel. When dry, it does not attack steel, and can therefore be transported in steel tanks. It is soluble in benzene, ether, chloroform, and petroleum ether. It reacts with alcohols to give esters of silicic acid. On partial hydrolysis (e.g., with ether – water mixtures), silicon oxychlorides, $Si_nO_{n-1}Cl_{2n+2}$, are formed as colorless, viscous liquids. These oxychlorides, together with the corresponding metallic chlorides, are formed when silicon tetrachloride reacts with metal oxides (e.g., of Mn, Cu, Ca, Zn, Mg, Ag, or Hg) in organic solvents [148].

3.2.1. Production

Silicon tetrachloride is prepared in the laboratory by the reaction of silicon or high-silicon ferrosilicon with dry chlorine at >400 °C. At lower temperature, Si_2Cl_6 and other subchlorides are also formed [15].

In industry, $SiCl_4$ is mainly produced by reacting ferrosilicon, pure silicon, or silicon carbide with chlorine. Other possible processes include the reaction of SiO_2 or a SiO_2/SiC mixture with carbon and chlorine (or with $COCl_2$ or CO/Cl_2 mixture). This older process, which uses silica sand as the cheap raw material, has attracted renewed interest since the introduction of the fluidized-bed reactors.

From Ferrosilicon (>90 % Si) or Pure Silicon and Chlorine. The reaction between silicon and chlorine is exothermic. Therefore, after the reaction has been initiated, cooling must be provided. Ferrosilicon, with a high silicon content, is cheaper than pure silicon, and due to the greater reactivity of the iron, is more readily chlorinated. However, the temperature must be maintained at >400 °C so that the $FeCl_3$ formed is removed, and blockages in the pipework are prevented.

In the Dynamit Nobel process, large pieces of ferrosilicon containing >90 % silicon are continuously fed into a furnace at >500 °C fitted with a cooling jacket. Silicon tetrachloride is formed together with iron chloride and the chlorides of the other elements present in the ferrosilicon, mainly aluminum chloride, calcium chloride, and titanium tetrachloride. The nonvolatile chlorides (e.g., $CaCl_2$) remain in the furnace, and are removed from time to time together with unchlorinated components (e.g., SiO_2).

The volatile chlorides pass out of the furnace and are then partially condensed by cooling. The collecting vessel is maintained at such a temperature that the $SiCl_4$ distils over while the $FeCl_3$ and $AlCl_3$ remain behind. Most of the $SiCl_4$ is then condensed out, and the residual gases are cooled to −35 °C, causing any remaining tetrachloride to separate.

The crude silicon tetrachloride still contains small quantities of iron and aluminum chlorides, and also some chlorine, titanium tetrachloride, and hexachlorodisiloxane formed by partial hydrolysis of $SiCl_4$ by the traces of water that enter the furnace during charging. This is purified by simple evaporation and condensation, followed by fractional distillation. In the evaporation process, which is also applied to the residues from the fractional distillation, chlorides of iron and aluminum remain behind along with some of the medium boiling point compounds, i.e., hexachlorodisiloxane and titanium tetrachloride. The crude distillate obtained is fractionated in a double distillation column.

It has been proposed that a molten salt reaction medium should be used [149], and that inert materials such as carbon, aluminum oxide, and silica should be added in both the batch [150] and the continuous process [151].

From Silicon Carbide and Chlorine.

$$SiC + 2\,Cl_2 \longrightarrow SiCl_4 + C$$

The advantage of using the readily available industrial-grade silicon carbide as the starting material must be balanced against the disadvantages that the reaction with chlorine starts at a higher temperature, and the heat of reaction is not sufficient to maintain the material at the reaction temperature without heating. Also, the carbon formed remains behind as a residue.

Silicon is added to the silicon carbide to facilitate the reaction. The chlorination is carried out in a vertical shaft furnace made of steel or cast iron lined with carbon plates. The downstream condensation system includes a spray of

liquid silicon tetrachloride to prevent blockage by the iron and aluminum chlorides formed from impurities in the raw material [152].

In a modified process, the chlorine is mixed with oxygen, which oxidizes some of the carbon formed in the reaction to carbon monoxide [153, 154]:

$$SiC + 2\,Cl_2 + 1/2\,O_2 \longrightarrow SiCl_4 + CO$$

From Silica, Carbon, and Chlorine. Information on the temperature required for the reaction of various silica modifications with chlorine and carbon is given in [155].

Chlorides of alkali metals or alkaline earths can be mixed with the finely powdered coke and kieselguhr or other silica-containing materials to lower the reaction temperature. The mixture is treated with chlorine at red heat [156]. In a variation of the process, the energy is provided by an electric arc, which is applied to the reaction mixture in a fixed [157] or fluidized bed [158].

As the reaction of SiO_2 with carbon and chlorine is endothermic, it is necessary to couple it with an energy-producing process, e.g., silicon and chlorine, ferrosilicon and chlorine, or silicon carbide and chlorine. In the Stauffer process [159], silicon carbide, silica sand, and coke are treated with chlorine gas in a fluidized-bed reactor. A separator removes any solid material from the gaseous reaction product, which is then cooled in heat exchangers. Silicon tetrachloride condenses out and is purified by the usual distillation process.

Other Processes. These include: treatment of silicon or a Si – Cu alloy with CCl_4 vapor at 260 – 300 °C [160], reaction of alkali metal silicofluorides (e.g., Na_2SiF_6) with $AlCl_3$ at 280 °C [161] or with $MgCl_2$ at 500 – 1000 °C [162], and recovery of byproduct silicon tetrachloride from the production of methylchlorosilanes (→ Silicon Compounds, Organic).

The formation of incrustations in a fluidized-bed reactor can be prevented if a mixture of metallurgical silicon and silicon carbide with silicates of iron, titanium, vanadium, or chromium is used. Increases in yield of up to 12 % have been observed [163].

Lower reaction temperatures, down to 200 °C, and the use of silicides, preferably calcium silicide, yields substantial amounts of tetrachlorosilane together with an appreciable amount of hexachlorodisilane [164, 165]. The conversion of higher chlorosilanes into tetrachlorosilane is effected by tertiary amines in catalytic amounts below 160 °C. Refluxing of hexachlorodisilane with 0.8 vol % of pyridine gave tetrachlorosilane [166].

3.2.2. Purification

The main aim of purification is to remove halides of boron and phosphorus by preferential hydrolysis, complexing agents, or the incorporation of adsorption stages in the distillation process. Examples include preferential hydrolysis of BCl_3 by adding water or ice [167, 168], adding substances to the distillation process that combine with BCl_3 such as CH_3CN and $(C_6H_5)_3CF$ [169, 170], substances that combine with PCl_3 such as $AlCl_3$ [171], and passing the silicon tetrachloride through adsorption columns charged with substances containing tertiary amine groups, quaternary ammonium groups [172], or water-containing oxides or silicates [173]. A countercurrent zone-melting process has also been developed for the purification of $SiCl_4$ [174].

Removing boron impurities is also accomplished by high-temperature hydrogenation, which converts boron trichloride, the chief impurity to volatile diborane [175]. The fact that considerable amounts of silicon hydrides, chiefly trichlorosilane and dichlorosilane, are formed as byproducts, is of no apparent disadvantage since both can now be used in high-purity silicon manufacture.

Low-loss optical fibers require precursors with extremely low contents of hydroxyl-containing impurities. These are probably chloro – hydroxy complexes of metals, mainly iron. They are removed by partial hydrolysis of the tetrachlorosilane with adsorption of the impurities on the in situ precipitated silica gel. The residual contaminant content is 12 ppm Fe, 2 ppm OH, and 18 ppm HCl [176].

3.2.3. Uses

High-purity silicon is produced by the thermal decomposition of $SiCl_4$ in the presence of

hydrogen, and highly dispersed silica is produced by flame hydrolysis of $SiCl_4$ (→ Silica, Chap. 6.1.1.).

Corrosion-resistant silicon coatings are produced on metal surfaces, e.g., steel and iron [177, 178], molybdenum, tungsten, tantalum [179], molybdenum, or tungsten [180] by heating the metal component in an atmosphere of $SiCl_4 - H_2$ or $SiCl_4$ at 1000 – 1400 °C.

3.3. Hexachlorodisilane

For years, hexachlorodisilane was a typical byproduct; its formation was suppressed as far as possible or a conversion to more versatile products carried out. It is now a compound of its own standing leading directly to the production of several special silicon products. The manufacturing processes, however, are still dominated by the basic reaction of silicon or silicides with chlorine giving a number of chlorosilanes, hexachlorodisilane being just one.

3.3.1. Production

To obtain hexachlorodisilane as a high share in a crude chlorosilane product mixture, conversion or degradation processes have been designed. Calcium silicide is the preferred raw material and a low reaction temperature of 200 °C is used [181]. Continuous production in a multicolumn reactor [182], and batch production [183] with a comproportionation step have been described:

$$Si_3Cl_8 + SiCl_4 \longrightarrow 2\,Si_2Cl_6$$

Reaction of ferrosilicon, with a silicon content of 50 %, and chlorine at 160 °C in a vibrating reactor gave 55 wt % hexachlorodisilane, and 44 wt % tetrachlorosilane with a 70 % ferrosilicon conversion [184, 185].

High-boiling residues, predominantly containing polychloropolysilanes, are cleaved by chlorine in a fluidized bed [186] at 250 – 450 °C.

$$2\,Si_3Cl_8 + Cl_2 \longrightarrow 3\,Si_2Cl_6$$

At 500 °C on α-alumina beads [187] comproportion of tetrachlorosilane is readily achieved, with a conversion of 70 %. The reverse reaction is carried out at a temperature of 700 °C aided by lithium – magnesium double oxides as catalysts and alumina as the carrier.

$$2\,SiCl_4 \longrightarrow Si_2Cl_6 + Cl_2$$

The reaction product consists of 50 % unchanged tetrachlorosilane, 40 % hexachlorodisilane, and 10 % higher homologues [188].

Liquid-phase chlorination allows a lower reaction temperature to be used. Using elemental silicon and a catalyst consisting of the chlorides of sodium, potassium, and zinc gives a product mixture that contains tetrachlorosilane, hexachlorodisilane, and tetrachlorodisilane in a weight ratio of 12 : 17 : 11 [189]. Suspension of silicides and antimony pentachloride can be chlorinated to hexachlorodisilane with 34 % conversion [190]. In a solvent mixture in which some components exhibit catalytic properties [e.g., perfluoroalkanes, tris(perfluoroalkyl)amines, and cyclic perfluoroalkyl ethers] elemental silicon reacts with chlorine at 150 °C [191] to give hexachlorodisilane and octachlorotrisilane.

3.3.2. Uses

In most of its applications, hexachlorodilane can be replaced by other special silicon compounds, but in some cases, the reactions take place at much lower temperature than with tetrachlorosilane or trichlorosilane. The deposition of elemental silicon by purely thermal decomposition has been carried out on silicon wire at 750 °C [192], on a quartz plate at 500 °C [193], or on quartz crucibles [194].

Hydrogen as a reducing agent has been used to make bulk polycrystalline silicon above 250 °C [195] or to produce atomic layers of silicon by homoepitaxy [196]. A viscous oil obtained by reacting hexachlorodisilane with tetrabutylphosphonium chloride at 200 °C can be pyrolyzed to give finely divided amorphous silicon [197]. The reaction of hexachlorodisilane with propane on graphite surfaces at 700 °C [198] gives β-silicon carbide. On a cobalt-containing substrate, silicon carbide whiskers are obtained [199]. Mixed carbides of silicon and titanium are made by hydrogenation of a mixture of hexachlorodisilane, titanium tetrachloride, and alkyl halide [200].

Optical fibers can be made by direct surface coating of preforms by flame hydrolysis of hexachlorodisilane [201, 202]. Ultrafine silica particles are formed by thermal decomposition of hexachlorodisilane in an oxygen atmosphere [203]. The method is suitable for the manufacture of quartz glass as a substrate for wave guides [204].

3.4. Other Silicon Chlorides

Hexachlorodisiloxane, intermediate or byproduct in oxidation or hydrolysis reaction, can be obtained as the chief product by reacting tetrachlorosilane with sulfur trioxide 500 °C.

$$2\,SiCl_4 + SO_3 \longrightarrow (Cl_3Si)_2O + SO_2 + Cl_2$$

By comparison, other monosilanes react differently. The bromide and hydride at room temperature give silicon dioxide, the fluoride, not at all even at 600 °C [205]. Formation and degradation of hexachlorodisiloxane can be shown by high-temperature reactions. It is formed from tetrachlorosilane and oxygen [206] together with other oligomeric siloxanes but with mono- and polycyclic siloxanes also. Thermodynamic studies indicate a certain metastability of halosiloxanes in general. No direct use has been made of hexachlorodisiloxane, conversion to chlorosilanes, i.e., recycling, is practised [207]:

An important intermediate is dichlorosilylene, the first reaction product of the attack of chlorine on silicon. Dichlorosilylene can be obtained directly in high-vacuum apparatus from the elements at 1250 °C [208, 209], and 1100 °C [210]; it is a transparent, amber-like solid.

3.5. Silicon Fluorides (Silicon Tetrafluoride, see → Fluorine Compounds, Inorganic, Chap. 5.1.)

Difluorosilylene Silicon tetrafluoride and silicon react at 1200 °C in a high vacuum, yielding a condensate with the composition $(SiF_2)_x$. This turns yellow on cooling with liquid air and ignites on contact with atmospheric oxygen. It loses its color on heating to −78 °C and becomes highly polymeric [211].

A plasma flame in an argon atmosphere [212, 213] can also be used as a reaction medium. A molar ratio of tetrafluorosilane to silicon of 0.8 : 1 gives a SiF_2 yield of 70 %.

Difluorosilylene can be used to produce silicon difluoride filaments [214]. The production of amorphous silicon films from SiF_2 by chemical vapor deposition leads to material with residual Si – F groups [215], which is claimed to afford a higher doping efficiency [216] for boron and phosphorus.

Reacting SiF_2 with methane and hydrogen in a glow discharge [217] gives a photoconductive amorphous silicon carbide. Silicides can be prepared by reacting hexafluorides of tungsten or molybdenum with difluorosilylene in a hydrogen atmosphere at 300 – 600 °C [218]. Oxidation of SiF_2 with oxygen, nitrous oxide, or nitrogen dioxide [219] gives silicon dioxide with residual Si – F groups, suitable for the manufacture of optical fibers.

3.6. Silicon Bromides

Silicon tetrabromide, tetrabromosilane, $SiBr_4$, M_r 347.7, is produced from silicon and bromine vapor at >600 °C. It is a colorless liquid, with *mp* 5 °C and *bp* 153 °C.

With ferrosilicon powder a 70 % yield of $SiBr_4$ is obtained. Crude tetrabromosilane is heated with zinc to remove residual bromine [220].

The main use for silicon tetrabromide is as a raw material for the production of silicon and its compounds. The reaction used is the reverse of the preparation method, i.e., it is pyrolytically decomposed [221, 222], usually together with silanes, using fluidized-bed processes [223], or

crystal growth techniques [224]. These techniques are also used in the manufacture of optical fibers [225–228] and photoconductive silicon [229].

In a plasma, tetrabromosilane is readily cleaved to the elements, and the deposition of the silicon layer is much faster than with tetrachlorosilane [230]. Tribromosilane can be produced by reacting metallurgical-grade silicon with tetrabromosilane at 600 – 800 °C in hydrogen atmosphere [231].

Other processes include the electrolytic deposition of silicon from solutions of silicon tetrabromide in aprotic organic solvents [232–234].

Silicon tetrabromide is also used to produce silicon nitride itself [235–238], as a coating, or to seal porous solids by exposing them to $SiBr_4$ vapor followed by reaction with ammonia [239]. Boron – silicon phases have been obtained by the copyrolysis of halogenated silanes and boranes [240].

Silicon tetrabromide is used as an auxiliary in the production of SnO_2 whiskers [241], the etching of aluminum and its alloys [242], and the copolymerization of dienes and vinyl compounds [243].

The entire series of bromosilicon hydrides are obtained by disproportionation [244]. With Amberlite A 21 as catalyst at 135 °C the major product is dibromosilane. Fluorobromosilanes are made by reacting tetrabromosilane with antimony trifluoride [245].

Fluorobromosilicon hydrides are made by reaction with alkyltin hydrides [246] at room temperature under reduced pressure:

$$SiBr_4 \xrightarrow{SbF_3} SiF_2Br_2 \xrightarrow{R_3SnH} HSiF_2Br$$

Comproportionation can be extended to the disilanes:

$$Si_2Br_6 \xrightarrow{Si_2Cl_6} Si_2Br_xCl_y$$

Separation of the products by distillation is difficult due to continuing halogen redistribution [247]. Since aryl groups on silicon can be cleaved by hydrogen halides in the presence of aluminum halide catalysts, this method can be used to prepare higher silicon bromides:

$$Ph_3Si-SiCl_3 \xrightarrow{HBr/AlBr_3} Br_3Si-SiCl_3$$

A well-defined, very reactive subhalide with the composition $(SiBr_2)_x$ is obtained by the reaction of $SiBr_4$ and silicon at 1150 – 1200 °C in a high vacuum. It is a transparent, almost colorless, amber-like solid, soluble in benzene, xylene, and CCl_4 [15,248,249].

3.7. Silicon Iodides

Silicon iodide, SiI_4, M_r 535.7, *mp* 121 °C, is a crystalline substance that is very sensitive to hydrolysis, decomposes into its elements on heating or on exposure to light, and reacts with oxygen at elevated temperature with liberation of iodine. SiI_4 is produced in 70 % yield by passing a carrier gas saturated with iodine vapor over silicon containing 4 % copper at 600 – 700 °C [15]. Silicon tetraiodide can be obtained on the kilogram scale in quantitative yield by passing nitrogen saturated with iodine vapor at ca. 200 °C over granulated silicon at 1150 – 1200 °C. Approximately 1.5 kg SiI_4 can be produced in 5 h by this method [250].

Other methods include the reaction of mixtures of iodine with bromine or chlorine with silicon at 600 – 800 °C [251], and heating alkali metal fluorosilicates with alkaline-earth iodides at 500 – 1000 °C [252] or with aluminum iodide at 300 °C [253].

Like the tetrachloride, tetraiodide can be used for the production of high-purity silicon by thermal decomposition (sometimes in the presence of hydrogen). The silicon tetraiodide can be purified beforehand by repeated sublimation and zone melting [254,255].

Silicon tetraiodide has some value as an additional reactant in the pyrolysis of silicon hydrides for the production of high-purity silicon [135], in the reduction of other silicon halides in a fluidized bed [256], and for the purification of silicon by zone melting [222].

Silicon tetraiodide is used as a starting material for the preparation of high-purity silicon films for solar cells by electrolyzing a solution of SiI_4 in aprotic organic solvents [232,233].

Special applications of silicon tetraiodide as a raw material include the manufacture of cermets [230], and of optical fibers with a germanium core and an outer coating of SiO_2 [257].

A subhalide having the composition of diiodosilylene has been reported [3].

4. Silicon Oxides (Silicon Dioxide, → Silica)

With the oxides, more so than with the halides, the growth of interest in use and production, i.e., formation, is brought about by the same driving forces as for the halides, i.e., electronics manufacture and environment protection.

Sources of silicon oxides are chiefly high-temperature processes in heavy industry like blast furnaces, carbide manufacture, coke making, and silicate processing. Main uses are found in high-tech precision preparation of chips, wafers, integrated circuits, layers, and coatings.

4.1. Silicon Monoxide

Silicon monoxide, SiO, M_r 44.06, is formed initially as a gas when SiO_2 and silicon, or SiO_2 and an amount of carbon insufficient for complete reduction, are heated to >1250 °C. It therefore plays a part in the industrial production of silicon and silicon carbide from SiO_2 and carbon, and in the production of ferrosilicon [258, 259].

At lower temperature (ca. 600 – 1000 °C), SiO disproportionates into silicon and silicon dioxide:

$$2\,SiO \rightleftharpoons SiO_2 + Si$$

There has, therefore, been prolonged controversy over the question whether SiO should be considered a true compound. Nevertheless, rapid chilling of the gas to room temperature enables the monoxide to be obtained in a solid metastable state. It has a wide range of uses as an additive in applied solid-state physics, and as a raw material in the production of other silicon compounds.

4.1.1. Production

A stoichiometric mixture of finely powdered SiO_2 and silicon in a reaction tube closed at one end is heated at its lowest point in a high vacuum for ca. 4 h at 1250 °C. A brown mixture of SiO_2 and Si, formed by disproportionation, collects in a short transition zone in the part of the tube that just protrudes from the furnace, and the SiO collects as black, compact, shellac-like masses in the parts further away from the furnace.

If an intimate mixture of SiO_2 and silicon is heated for 9 h to 1300 °C and rapidly chilled, cubic crystals of SiO are formed [15]. On an industrial scale, the monoxide can be produced by heating SiO_2 with silica, carbon, or silicon carbide to 1500 – 1800 °C in a resistance furnace [260, 261].

Heating the vapors of the reaction

$$SiO_2 + Si \xrightarrow{1500\,^\circ C} 2\,SiO$$

to 1800 °C in an ammonia atmosphere gives amorphous silicon monoxide powders [262].

Silicon monoxide can be made directly in the form of fibers by reducing sand flour with methane at 2500 °C in a fluid-wall reactor [263].

The formation of silicon monoxide by side reactions or as a byproduct of the main process takes place in the course of a number of industrial production streams. In terms of chemical categories these production steps are based on reductions as well as oxidations.

$$SiO_2 \begin{matrix} + Si \\ + SiC \\ + C \end{matrix} \longrightarrow SiO \longleftarrow \begin{matrix} Si \\ SiC \\ SiMe \end{matrix} + O_2$$

4.1.2. Properties

At room temperature, silicon monoxide is a light brown, finely divided powder, or, if it has been produced by slow condensation, it is a black or very dark brown, shellac-like, glassy mass. The lower limit of stability for gaseous SiO is not below 1025 °C, and is very probably >1175 °C [264]. The best temperature range for its production from SiO_2 and Si is 1200 – 1400 °C [265–267].

At 600 °C, SiO decomposes in several hours, at 700 – 900 °C in ca. two hours, and at 1000 – 1200 °C almost instantaneously into SiO_2 and silicon [266, 268]. Oxygen causes surface oxidation to SiO_2 even at room temperature, and complete oxidation takes place at ca. 500 °C.

Finely divided SiO is pyrophoric and burns with flame formation if there is rapid access of air.

With the increase in the number of possible uses for SiO, the silicon – oxygen system has been the subject of extensive investigations [269], particularly with regard to suppressing the formation of SiO during the production of high-purity silicon [270], and of Si – O – N mixed phases in atmospheres containing O_2 and N_2 [271].

4.1.3. Uses

Silicon monoxide is used in small quantities to produce protective films on semiconductors [272–274], vidicon targets [275], and in antireflective coatings on optical glass and plastics [276–279]. Silicon monoxide prevents the formation of anatase in rutile coatings on glass [280]. In entertainments electronics and data processing, silicon monoxide is used in recording tape, other types of data storage media, data transfer heads [281, 282], and in the alignment of liquid crystals for digital displays [283, 284]. Other applications include the coloring of glass surfaces by the simultaneous or sequential deposition of metals and silicon monoxide [285].

Another application of silicon monoxide electronics is the manufacture of heat-resistant films and devices in which corrosion resistance is required. It can be used as a heat-resistant protective layer in laser recording media [286], and in multilayer thermal heads for thermographic printers [287]. Multilayer devices consisting of aluminum, germanium, and silicon monoxide are selective solar absorbers for thermal conversion [288]. Ceramics consisting of silicon carbide whiskers in a graphite matrix can be reinforced by decreasing the porosity by filling the voids with silicon prepared in situ [289].

Silicon monoxide is used as a raw material, a construction material, and as an auxiliary. The best known application is the oxidation of gaseous silicon monoxide to amorphous finely divided silica [290], (see → Silica, Chap. 6.2.). Other uses include the production of silicon carbide [291, 292], silicon nitride [293–295], Si – O – N mixed phases [296], and cermets [297, 298]. Silica can be removed from silica-containing materials (e.g., kaolin) by adding silicon and heating the mixture at 1450 °C in a vacuum [299–301]:

$$Al_2O_3 \cdot 2\,SiO_2 + 2\,Si \longrightarrow Al_2O_3 + 4\,SiO_{Gas}$$

Silicon monoxide can be used to remove phosphorus from blast furnace slag, allowing it to be recycled [302].

Hard coatings of SiO_2 on metals, especially on metallic mirrors, can be produced by deposition of SiO from the vapor state (→Thin Films). The SiO is then oxidized by atmospheric oxygen to form SiO_2.

In the production of silicon nitride ceramic powders, silicon monoxide is reacted with a reducing atmosphere consisting of a mixture of ammonia and hydrocarbons at 1000 °C. When methane is used as sole reductant, the product is cubic β-silicon carbide [303].

A convenient method to prepare members of the halosilane family is the reaction of silicon monoxide with hydrogen halides [304].

Low-silicon metals are produced by effecting silicon depletion of the melt by limited oxidation. In the production of high-purity vanadium, vanadium pentoxide is added to the melt and the silicon monoxide formed is evaporated [305]. Silicon in molten indium is oxidized with water in a hydrogen atmosphere at 800 °C; ca. 90 % of the initial silicon content is converted to SiO [306].

4.2. Silicon Sesquioxides

Depending on temperature and pressure, the following disproportionation steps can take place:

$$4\,SiO \rightleftarrows Si_2O + Si_2O_3$$
$$Si_2O_3 \rightleftarrows SiO + SiO_2$$

When the monoxide is evaporated at reduced pressure the vapor invariably condenses as the sesquioxide, Si_2O_3 [307].

The reaction of sulfur trioxide with hexabromodisilane at room temperature affords an almost quantitative yield of the sesquioxide; no cleavage of the Si – Si bond takes place [308]:

$$Br_3Si{-}SiBr_3 + 3\,SO_3 \longrightarrow Si_2O_3 + 3\,SO_2 + 3\,Br_2$$

The sesquioxide can be prepared from hexachlorosidilane by hydrolysis via a sol – gel route [309].

Polymeric silicon sesquioxide can be prepared by thermal dehydrogenation of silicon oxyhydride in high vacuum [310].

$$2\,HSiO_{1.5} \xrightarrow{1000\,^\circ C} Si_2O_3 + H_2$$

Silicon sesquioxide can be prepared in situ on surfaces. Plasma – vapor deposition from a mixture of monosilane and nitrous oxide [311] gives a moisture-resistant film of silicon sesquioxide, used as a protective layer for *p*-Si substrates. On polycarbonate sheets, Si_2O_3 layers are prepared by electric discharge [312] or vacuum deposition [313]. On polyethylene [314] a Si_2O_3 layer has been applied by sputtering with an oxygen plasma, using silicon monoxide as the silicon source.

The suboxides, the sesquioxide being the predominant species, are present in semiinsulating films of polycrystalline silicon [315]. Annealing at 1100 °C converts the other suboxides to the sesquioxide only. The suboxides are also formed on etched surfaces of silicon [316] and in layers obtained by silicon implantation oxidation [317]. Thermal annealing leads to a composition corresponding to that of the sesquioxide when carried out at 600 °C.

Less for effects in high-tech physics than essentially in basic chemical processes, the sesquioxide has found quite different applications. Cleaning and purification spans from that of arsenic vapors [318] to the treatment of waste fluid from sweet potato processing [319]. Highly permeable membrane separation elements are made from a ceramic material based on alumina and silicon sesquioxide [320]. The material is stable in aqueous environment having a water penetration rate of 4.2 m^3/h. In ceramic material the sesquioxide has been used as an oxidizing agent during manufacture [321] and as bits for welldrilling [322]. Wear resistance is much lower though, than for tungsten carbide.

4.3. Other Silicon – Oxygen Compounds

Oxyhydrides of the composition $(HSiO_{1.5})_x$ are obtained by the hydrolysis of trichlorosilane [323–325]. In organic solvents the product is formed as an amorphous powder or as transparent mica-like flakes [310], depending on the type of solvent. Well-defined, low molecular oligomers – the smallest [326, 327] being a cage of 8 silicon atoms arranged at the corners of a cube with 12 oxygen atoms forming the bridges along the edges – can be prepared by hydrolysis in a two-phase system [328–330]. Oligomers with *x* an even number ranging from 8 to 16 are obtained.

The Si_8-cube is also the smallest cage in zeolite structures; it is the 4 – 4 secondary building unit in zeolite A. Since the silver zeolite reacts with water evolving oxygen, ligand-to-metal charge transfers in the Si_8-cube are of interest in the context of processes involving photolysis of water by visible light [331]. By photochemical oxidation of tetrachlorosilane the trichlorosilanol is produced, a compound existing only in equilibria with others [332]. Utilizing structural possibilities new silicon – oxygen compounds were prepared, the oxygen taking part as the donor atom in penta-coordinate silicon alkoxide complexes. Alkoxysilanes react with metal hydrides to trialkoxy anions which then rearrange to the tetraalkoxy anion [333]

$$4\,HSi(OR)_3 + 4\,KH \longrightarrow 4\,\&H_2Si(OR)_3]^-K^+$$
$$\longrightarrow 3\,\&HSi(OR)_4]^-K^+ + SiH_4 + KH$$

Likewise the reaction of silica with glycol is made possible through penta-coordinate complex formation around the silicon atom [334].

5. Silicon Sulfides

Silicon sulfide, SiS_2, M_r 92.18, *mp* 1090 °C, sublimation point 1130 °C, forms white, asbestos-like needles, which readily hydrolyze. It is formed from silicon and sulfur at 1100 – 1300 °C [335], but preferably at >1400 °C [336, 337]. Silicides react with sulfur at >700 °C, hydrogen sulfide at 1100 – 1200 °C, or sulfur chlorides (e.g., S_2Cl_2, at its boiling point of 135 °C). The SiS_2 formed must be recovered from the other reaction products (e.g., MgS) by sublimation.

The simplest laboratory method consists of a combination of these two processes. The reaction of Mg_2Si with S_2Cl_2 is used to start the reaction of silicon with sulfur. A mixture of 3 parts by weight of Si, 0.5 parts by weight of Mg_2Si, and 8 parts by weight of sulfur is impregnated

with 1 part by weight of S_2Cl_2 in a glass tube and heated at one point with a small flame. The reaction starts with a glow. The SiS_2 formed is sublimed off in a vacuum [336].

On a large scale, SiS_2 can be produced by the thermal decomposition of esters of thiosilicic acid. The ethyl ester decomposes at 300 °C:

$$Si(SC_2H_5)_4 \longrightarrow SiS_2 + 2\,C_2H_5SC_2H_5$$

The reaction temperature can be lowered to 200 °C by adding sulfur [336, 338].

The formation of silicon – sulfur compounds, including SiS_2, has also been observed during the drilling of holes in crystalline silicon plates by laser beams in an atmosphere of sulfur hexafluoride [339].

Direct synthesis from the elements is still being carried out and improved. Continuous feeding into reactors [340] allows a lower reaction temperature of 800 °C to be used. Under a pressure of 2.5 – 6.0 GPa and 1000 – 1200 °C the conversion to the sulfide is almost complete, yielding four different polymorphic modifications of silicon sulfide [341].

Silicon disulfide can be conveniently obtained from silica, carbon, and sulfur vapors in an atmosphere of hydrogen sulfide above 1130 °C [342]. The product consists of glassy solid and needle-like crystals.

Silicon disulfide reacts with ammonia to give silicon nitride, Si_3N_4. Between 800 and 1400 °C the nitride is obtained as an amorphous powder. If a lower temperature and silicon disulfide in the form of whiskers are used, the product retains the morphological characteristics and consists of silicon nitride whiskers [343].

Because of their volatility, the formation of silicon sulfides at high temperature is utilized for desiliconization in purification processes. For example, pure zirconium oxide is obtained by conversion of silica impurities followed by vaporization at 1300 °C [344]:

$$SiO_2 + C + 2\,S \longrightarrow SiS_2 + CO_2$$

Glassy phases containing silicon disulfide can be used as solid electrolytes in conducting glasses for batteries, especially microbatteries. A system consisting of a $Li_2S - SiS_2(P_2S_5)$ phase between a $Li/V_2O_5 - TeO_2$ couple has an open circuit voltage of 2.8 – 3.1 V [345, 346].

From a melt of equimolar amounts of silicon disulfide and lithium sulfide, lithium silicon sulfide is obtained in three phases: equilibrium, metastable crystalline, and glassy Li_2SiS_3 [347]. The conductivity is greatly enhanced by the addition of lithium bromide [348, 349], iodide [350, 351], or chloride [349]. The highest conductivity reported [333] is 1.8 s/cm at 25 °C, measured in a glass consisting of the phase $0.24\,SiS_2 - 0.36\,Li_2S - 0.4\,LiI$.

Glassy phases containing silicon disulfide are also obtained by the action of elemental silicon on arsenic sulfide [352]

$$5\,Si + 2\,As_2S_3 \longrightarrow 2\,SiS_2 + 2\,As_2Si$$

6. Silicon Nitrogen Compounds

The prevailing chemical of this class is the silicon nitride, Si_3N_4, a solid of regular valence composition that has found commercial use in high-temperature engineering ceramics and in the form of whiskers as reinforcing material in cermets. A number of processes are now available to produce the nitride as a powder, a film, or as needles.

For nitride production, choice of process is largely influenced by the material, of having it at disposal or having to dispose of it. Byproducts and wastes from other production lines of silicon chemistry manufacturing decide on availability and necessity.

The direct synthesis from the elements has been carried out only to study the effects on silicon surfaces. Between 1350 and 1450 °C the nitride is formed [353]. Nitridation is enhanced by the presence of iron in silicon and by hydrogen in the nitrogen atmosphere, the latter also increasing the ratio of α-/β-silicon nitride [354]. Gas-phase reactions of monosilane and ammonia [355] can be used for deposition of silicon nitride.

Of the silicon halides, the tetrachlorosilane can be reacted with a nitrogen – hydrogen mixture giving amorphous nitride [356]

$$3\,SiCl_4 + 2\,N_2 + 12\,H \longrightarrow Si_3N_4 + 12\,HCl$$

Hexachlorodisilane is useful to obtain silicon nitride whiskers [357] by chemical vapor deposition in the course of the reaction with ammonia. Between 950 and 1700 °C the resulting

whiskers are coiled in shape; they exhibit good dispersibility [358]. The reaction can be extended to include other halide derivatives of disilane [357]. Finely divided nitride is obtained using silicon fluorides as the silicon source [359]. Making silicon nitride from the disulfide can result in needles [343,360]. By reacting evaporated silicon disulfide with ammonia above 1130 °C [361] or in a two-step process first at 800 °C, then at 1400 °C [362] the product is a powder of α-Si_3N_4. During the synthesis of silicon carbide the nitride is formed through contact of the carbide with nitrogen at temperatures below 2050 K [363]. For a variety of silicon or nitrogen sources the reaction temperature of 900 to 1100 °C seems practical, the energy furnished by a plasma induced by radio frequency discharge [364]. A critical review of thermal plasma reactions leading to silicon nitride from different silicon sources presents data on the thermodynamics and nucleation kinetics [365]; i.e., a high supersaturation of silicon should always be avoided.

7. Silicon Borides

The long-known binary silicon borides, SiB_3 and SiB_6, are produced simultaneously when the constituent elements are heated between carbon electrodes in an electric furnace [366]. Phases with the composition SiB_4 have since been produced and evaluated for a large number of application areas.

The compound SiB_4 is produced from its elements at 1090 – 1370 °C by resistance heating and is purified by treatment with a mixture of nitric and hydrofluoric acids. It can also be produced from boron trioxide and silicon [367]. It is used as a refractory material in blast furnaces. Its use as a catalyst for the liquid-phase oxidation of alkenes with organic hydroperoxides to form oxiranes has also been reported [368]. Mixed phases of silicon borides and molybdenum silicides resistant to oxygen up to 1600 °C are prepared by sintering a pasty mixture of these materials with colloidal silica at 1300 – 1500 °C. They can be used as abrasives and as highly refractory materials [369].

1. Introduction

Organosilicon compounds are substances that contain at least one organic group directly bonded to silicon via a silicon–carbon bond. They can be subdivided into two main groups: monomeric compounds and polymers. Of the latter, the polymeric silicones, in which organosilicon units are linked by Si–O–Si bonds, are economically the most important. They are obtained from monomeric organohalosilanes by hydrolysis or methanolysis followed by polycondensation. Silicone production is thus the largest consumer of monomeric silanes. Polysilanes – compounds with Si–Si bonds – are increasing in importance. The monomeric organosilicon compounds are important components in a wide range of other applications apart from silicone chemistry. Their uses as auxiliary materials and as protecting groups in organic syntheses, as

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_021

catalyst components in olefin polymerization, as protective agents for buildings, and as precursors for silicon carbide and silicon nitride coatings by chemical vapor deposition are important. An area with great potential is that of biologically active silicon compounds. Some organosilicon-based pharmaceuticals and crop protection agents are already on the market. Further developments in this area include silylated fragrance materials.

History. The first organosilicon compound, tetraethylsilane, was obtained in 1863 by FRIEDEL and CRAFTS by treatment of diethylzinc with tetrachlorosilane (Eq. 1) [15]. Two years later they prepared tetramethylsilane from dimethylzinc by an analogous method [16]. Subsequently, a series of new organosilicon compounds was prepared by treating tetrachlorosilane or tetraethoxysilane with organometallic reagents (Eq. 2). The work of PAPE, LADENBURG, and KIPPING was associated with this [17, 18]. The introduction of Grignard reagents into organosilicon chemistry by DILTHEY and KIPPING in the early 1900s was an important advance (Eq. 3) [19].

$$2\,Et_2Zn + SiCl_4 \longrightarrow Et_4Si + 2\,ZnCl_2 \quad (1)$$

$$Si(OEt)_4 + Et_2Zn \xrightarrow{Na} Et_xSi(OEt)_{4-x} \quad (2)$$

$$SiCl_4 + EtMgI \longrightarrow Et_xSiCl_{4-x} \quad (3)$$

Despite much research, organosilicon compounds remained a laboratory curiosity for a long time, and in 1936, KIPPING – in a summary of his investigations of nearly 40 years – still maintained that for this class of compound, important applications were neither known nor to be expected [18]. At the same time, however, Corning Glass and General Electric in the United States had already recognized that insulating materials resistant to high temperature could be produced from these compounds [20]. With the development of the direct synthesis – the production of methylchlorosilanes by the reaction of silicon with chloromethane in the presence of a catalyst – by ROCHOW [21] in the United States and MÜLLER in Germany [22], the basis for economical silicone production was finally established. Another milestone was the discovery in 1947 of the hydrosilylation reaction, in particular the oxidative addition of Si–H groups to carbon – carbon multiple bonds [23]. The discovery that this reaction can be controlled by using transition-metal catalysts [24] allowed economical access to a large number of new organosilicon compounds and their use in silicone chemistry and other areas.

Nomenclature. In nearly all organosilicon compounds, particularly the industrially important ones, the silicon atom is tetravalent. Most organosilicon compounds therefore contain tetracoordinate silicon. Compounds with higher coordination numbers occur as reactive intermediates in many reactions, while compounds with multiple bonds to silicon exhibit lower coordination numbers. The group of biologically active silatranes [25] with pentacoordinate silicon and the numerous investigations into hypervalent organosilicon compounds [26], whose chemistry may achieve industrial importance in the future, are also worth mentioning. In principle, organosilicon compounds can be regarded as derivatives of silane (SiH_4) in which the hydrogens have been replaced completely or partially by hydrocarbon groups:

$$SiH_4 \xrightarrow[-nH]{+nR} R_nSiH_{4-n} \quad (4)$$

The remaining hydrogens can also be replaced by functional groups X. The resulting compounds are known as mono-, di-, or trifunctional organosilicon compounds, depending on the number of groups present in the molecule.

$$R_nSiH_{4-n} \xrightarrow[-mH]{+mX} R_nSiH_{4-n-m}X_m \quad (5)$$

Almost all monomeric organosilicon compounds that contain tetracoordinate silicon can be derived from this general formula.

For a more precise classification the R groups are divided into "organofunctional" and "simple" organic groups. The latter are generally alkyl or aryl groups to which, however, a certain degree of functionality must be assigned, since it is possible to exchange alkyl groups for other alkyl or aryl groups, hydrogen, or other substituents in the presence of catalytically active Lewis acids such as $AlCl_3$. Alkyl groups can also be converted into organofunctional groups: e.g., chloromethylated silanes are formed in the

chlorination of methylsilanes under UV irradiation. Examples:

Simple organic groups:	$-CH_3$, $-C_2H_5$, $-C_6H_5$
Organofunctional groups:	$-CH=CH_2$, $-C\equiv CH$, $-CH_2-CH=CH_2$, $-CH_2Cl$, $-\underset{\underset{O}{\|}}{C}-R$, $-CH_2CH_2NR_2$, $-CH_2-\underset{\underset{O}{\diagup\diagdown}}{CH-CH_2}$
Silicon-functional groups:	halogens, $-NH_2$, $-NR_2$, $-S-C\equiv N$, $-OR$, $-OH$ (silanols), $-OM$ (metal silanolates)

The special IUPAC nomenclature rules for organosilicon compounds have not yet been issued. According to general IUPAC rules, tetravalent organosilicon compounds are called silanes and the ligands should be listed in alphabetical order, but hydrogen should not be named. The following order, which deviates from this, has become established in the technical literature: organofunctional ligand, simple organic ligand, alkoxy groups, halogen.

Compounds in which silicon is incorporated into a ring are known as silacyclo compounds (e.g., silacyclobutane). Silenes contain a Si–C double bond. Silicon chains and rings are named according to the number of silicon atoms: disilane, trisilane, cyclohexasilane. Certain functional groups have their own names: ≡Si–OH = silanol, ≡Si–SH = silanethiol, ≡Si–O–Si≡ = siloxane. Some examples of nomenclature are:

Chemical formula	Name
Me_4Si	tetramethylsilane
$Me(H)SiCl_2$	dichloromethylsilane
Ph_2SiH_2	diphenylsilane
$H_2NCH_2CH_2(Me)Si(OMe)_2$	2-aminoethyldimethoxymethylsilane
Me_3SiOH	trimethylsilanol
$(Me_2SiO)_3$	hexamethylcyclotrisiloxane
$Me_2(H)SiSiH_2Me$	1,1,2-trimethyldisilane
$(Me_2Si)_6$	dodecamethylcyclohexasilane

Structure and Reactivity. Like carbon, silicon preferentially assumes a tetrahedral arrangement of its four valences in forming compounds. The larger atomic radius of silicon compared to carbon (C, 77 pm; Si, 177 pm) leads, for example, to lower barriers to rotation at silicon–element bonds than in the corresponding carbon compounds. Also, the completely different bond energies of silicon and carbon (for examples, see Table 1) and the different electronegativities of the two elements (Pauling electronegativities: Si = 1.8, C = 2.5) result in the organic chemistry of silicon being fundamentally different from that of carbon. The high affinity of silicon for oxygen is the reason why only compounds with Si–O bonds (SiO_2, silicates) occur naturally. Although addition reactions to unsaturated systems are important in synthetic organic chemistry, in silicon chemistry this type of reaction is primarily of academic interest because, thus far, species with multiple bonds to silicon have been difficult to prepare. If the problem of synthesizing compounds with Si–C or Si–Si double bonds economically is solved, the door could be opened to a new sphere of industrial organosilicon chemistry. In organosilicon chemistry, S_N2 nucleophilic substitution at silicon plays a much more important role than in the case of carbon. Depending on the nucleophile, an Si–C bond can be formed or broken. It is particularly likely to be broken if a functional group is present in the β-position (β-effect). Nucleophilic substitution always occurs particularly readily if the bond strength of the new silicon–substituent bond is significantly higher and no steric hindrance occurs. Because of this, alkylhalosilanes react with water, for example, with the loss of hydrogen halide to form silanols in the first step (Eq. 6). The latter can then react further under alkaline (nucleophilic attack of OH^- at the silicon atom) or acid (electrophilic attack of H_3O^+ at the oxygen atom) conditions to give oligo- or polysiloxanes (see → Silicones, Chap. 2.1.1.).

Table 1. Examples of bond energies for silicon and carbon [27]

Compound	Bond energy, kJ/mol	
	X = Si	X = C
H_3X-H	378	439
H_3X-CH_3	343	378
H_3X-OH	452	386
H_3X-F	565	460
H_3X-Cl	381	354
H_3X-SiH_3	310	343

$$R_{4-n}\,SiX_n + n\,H_2O \longrightarrow R_{4-n}\,Si(OH)_n + n\,HX \quad (6)$$

The conversion of Si–X into Si–O is facilitated by the ability of the silicon atom to form pentacoordinate transition states.

The high reactivity of Si–X bonds (X = halogen, N, S), together with the high chemical and thermal stability of bonds between silicon and simple organic groups, is characteristic of organosilicon compounds. These properties have led to the broad range of applications of this class of compounds.

Because of the very large number of known organosilicon compounds, the most important fundamental synthesis routes for organosilanes are discussed first. Following this the classes of organosilicon compounds that are particularly important industrially and economically are discussed.

2. Fundamental Synthetic Routes for Organosilicon Compounds

2.1. Direct Synthesis of Organohalosilanes

The process described independently by Rochow [21] and Müller [22], involving the direct reaction of haloalkanes with elemental silicon in the presence of a copper catalyst, is currently the standard synthesis used by all major silicone producers.

$$\begin{array}{l} Si + RX \xrightarrow{250-320\,^{\circ}C} R_3SiX + R_2SiX_2 + RSiX_3 + \ldots \\ R = CH_3: Cat. = Cu \\ R = C_6H_5: Cat. = Ag \end{array} \qquad X = F, Cl, etc. \quad (7)$$

Although the process is, in principle, applicable to any organic halide, it has been successful commercially only in the production of methylchloro- and phenylchlorosilanes. Longer- chain haloalkanes and unsaturated compounds such as vinyl chloride or allyl chloride generally give low yields of organosilanes, consisting of mixtures that are difficult to separate. Similarly poor results are obtained when polychlorinated compounds such as α,ω-dichloroalkanes or dichloromethane are used [28–30]. For this reason, only the reaction of silicon with chloromethane is described below.

Mechanism. Although the mechanism of the direct process has been investigated intensively since its discovery, it has not yet been fully elucidated. A detailed review of older work on this subject can be found in [31], while more recent studies are described in [32]. The reaction of chloromethane and silicon in the presence of copper is a heterogeneously catalyzed gas–solid reaction. In the first step the copper catalyst and silicon react to form Cu_3Si. Whether this η-phase is the actual reactive species has been disputed, but it does guarantee that silicon and copper are in close proximity. This permits the formation of active Si–Cl groups on the surface via the chlorination of silicon by CuCl. The latter is formed by the decomposition of a copper–chloromethane adduct, which also yields hydrogen, methane (and other hydrocarbons), and carbon as side products. Since the Si–Cl species are formed next to the copper–chloromethane adducts, the transfer of a methyl group with formation of a surface-bound Cl–Si–Me transition state is probable. Further chloromethane transfer finally leads to Me_2SiCl_2, which is liberated. CuCl remains behind at the catalyst surface and can initiate a new cycle. The chain reaction can be terminated by combination of two surface-bound Si–Cl groups or by reaction of Si–Cl with CuCl. The resulting $SiCl_2$ groups give $MeSiCl_3$ by further reaction with a Cu–MeCl adduct. The formation of Me_3SiCl and other side products can be explained similarly. Methyl radicals or silylenes in the gas phase [33] are not important for propagation of the reaction.

Promoters. If copper alone is used as catalyst in the direct synthesis a slow reaction occurs with low degrees of silicon conversion and unsatisfactory selectivity for the target product dichlorodimethylsilane. By using metallic promoters, both the activity of the catalyst mixture and the selectivity of the synthesis can be improved. The addition of antimony, cadmium, aluminum, zinc, tin, or combinations thereof has been found to be effective. For example, a catalyst mixture with 94.49 wt % Si, 5 wt % Cu, 0.5 wt % Zn, and 0.01 wt % Sn gave a dichlorodimethylsilane selectivity of 80 mol % [34]. A selectivity of 90 % has been reported with a similar catalyst system [35]. The promoter concentration is critical; for example, too high a tin content inhibits reaction. The action of promoters can be explained as follows: they facilitate the transfer of chlorine and methyl groups to silicon and the diffusion of silicon into copper. Further

information is given in [34] and references cited therein.

Nonmetals such as phosphorus can also be used as promoters [36].

Product Distribution. The direct process never follows exactly the "ideal equation," according to which only dichlorodimethylsilane should be formed. Many other products are formed in varying quantities in temperature-, catalyst-, or raw material-dependent side reactions. Besides methyltrichlorosilane and chlorotrimethylsilane, incompletely substituted silanes, such as dichloromethylsilane, are also formed. Furthermore, the crude silane mixture contains saturated and unsaturated hydrocarbons and 3–8 % disilanes of general formula $Me_nSi_2Cl_{6-n}$. Table 2 lists the distribution of the main monomeric silicon-containing products and their boiling points. The compounds Me_4Si [*75-76-3*], $HSiCl_3$ [*10025-78-2*], $SiCl_4$ [*10026-04-7*], and others are also formed in small amounts. All the organosilicon compounds formed can be used in silicone chemistry or other fields, the disilanes generally after catalytic or thermal cleavage to monosilanes. The product ratio causes problems in certain cases. The target is to obtain a crude silane mixture in which the individual silanes are obtained as closely as possible to the ratio in which they will be used in the production of functional silanes and silicones, by means of suitable reaction conditions. Fortunately, dichlorodimethylsilane, which is particularly important, is formed in ca. 80 % yield. However, with chlorotrimethylsilane, chlorodimethylsilane, and dichloromethylsilane, shortages sometimes occur. These can be counteracted by altering the product ratio in the direct synthesis via addition of gases or metals.

Table 2. Main monomeric silicon-containing products of direct chloromethylsilane synthesis

Compound	*bp*, °C	Proportion in the crude silane, wt %
Me_2SiCl_2 [*75-78-5*]	70	70–90
$MeSiCl_3$ [*75-79-6*]	66	5–15
Me_3SiCl [*75-77-4*]	57	2–4
$MeHSiCl_2$ [*75-54-7*]	41	1–4
Me_2HSiCl [*1066-35-9*]	35	0.1–0.5

Zinc, magnesium, or aluminum in quantities up to 10 % or more has a strong alkylating effect via methylmetal halides formed as intermediates, so that the content of chlorotrimethylsilane in the crude silane can increase to 5–20 %. The metals ultimately act as halogen scavengers, forming the halides $ZnCl_2$, $MgCl_2$, or $AlCl_3$ [37, 38].

Calcium silicide (10–80 % Ca) reacts with chloromethane in the presence of zinc and copper as catalysts to give a mixture with a high proportion of more highly alkylated silanes (ca. 61 % Me_3SiCl and ca. 8 % Me_4Si) [39].

The proportion of hydrogen-containing organochlorosilanes can be increased considerably by adding H_2 [40] or HCl [41]. A $MeHSiCl_2 + Me_2HSiCl$ selectivity of > 80 mol % has been reported [42]. If silicon is reacted with HCl alone, $HSiCl_3$ and $SiCl_4$ are obtained.

Raw Materials. Formerly, ca. 97 % pure silicon was used. After the significant effect of even small quantities of added metals on the selectivity of the reaction and the catalyst activity was recognized, a purity of > 99 % is now aimed for. The impurities are generally aluminum, calcium, iron, and titanium. The presence of certain elements (e.g., Pb), which act as inhibitors, is particularly critical. Even 50 ppm of lead in the catalyst mixture halves the silicon conversion, and the Me_2SiCl_2 selectivity decreases considerably. The reactivity of silicon depends on its morphology, which can be affected by the conditions under which liquid silicon is cooled in the production process.

The purity of other raw materials should also be as high as possible. Copper, produced by cementation or electrolysis, must therefore be subjected to further purification. Partially oxidized copper is used, whose average composition is approximately Cu_2O. The use of a Cu–Si alloy or other copper compounds (e.g., CuCl or copper oxalate) is also possible [43]. Promoter elements such as zinc are used either as the metal, the oxide, or the chloride. Most producers obtain chloromethane by treating methanol with hydrogen chloride. In this way the hydrogen chloride formed in the conversion of organochlorosilanes to silicones can be recycled. If methanolysis is carried out instead of hydrolysis (Eq. 8), chloromethane is formed directly and can be recycled into the reaction after purification.

$$2 \equiv SiCl + 2\,CH_3OH \longrightarrow \equiv Si-O-Si\equiv + 2\,CH_3Cl + H_2O \quad (8)$$

Production and Composition of Catalyst Mixture. Silicon and the copper catalyst are either finely ground separately and then mixed with other catalyst components (promoters) or used in the form of a ground copper – silicon alloy. A particularly active catalyst mixture is obtained by atomizing silicon or Cu–Si alloys, which may already contain promoters [44]. During grinding the particle size must be adjusted so that homogeneous fluidization is obtained in the fluidized-bed reactor. For silicon the particle sizes are 30 – 350 µm, and for the copper catalyst, 5 – 30 µm. The catalyst mixture can be activated before use by tempering at 1000 °C in a stream of N_2 or preferably H_2. The direct synthesis, however, also activates the catalyst mixture. Usual catalyst mixtures contain 2 – 6 % copper and 0.05 – 0.5 % zinc. Other promoters such as antimony or tin can also be added in small amounts [35, 45].

Industrial Process. The catalyst mixture is introduced into a fluidized-bed reactor and fluidized with a strong, tangentially introduced stream of chloromethane at ca. 300 °C and 2 – 5 bar (Fig. 1). The gas phase is partially freed from solid components in a cyclone at the head of the reactor, and separated solids are returned to the reactor. The fine portion passing through the cyclone enters the crude silane after condensation of the gas stream and is isolated during workup. Part of it can then be reprocessed. Condensation gives gaseous chloromethane and a crude liquid silane mixture. After purification, chloromethane is recycled to the reactor, and the crude silane mixture is distilled. Since silicon is consumed in the reaction and some of the catalyst is entrained in the gas stream, new catalyst mixture must be added continually. Its composition in the reactor must be kept as constant as possible. Silicon conversions of 90 – 98 % are achieved, and chloromethane conversions of 30 – 90 %, depending on process conditions (pressure, reactivity of the catalyst mixture, etc.). The strongly exothermic direct synthesis requires precise and effective temperature control because high time – space yields and high selectivity for dichlorodimethylsilane are possible only at ca. 300 °C. This is achieved by several measures, which generally supplement each other. Heat is removed by a reactor cooling jacket and sometimes by a heat exchanger in the reactor. The reaction can be slowed by pumping in an inert gas so that less heat is liberated. Thorough mixing of the catalyst mixture in the CH_3Cl stream is particularly important.

Figure 1. Production of chloromethylsilanes
a) Preheater; b) Reactor; c) Catalyst mixture; d) Cyclone; e) Heat exchanger; f) Crude silane container; g) MeCl purification; h) Compressor; i) MeCl container; j) Heating/cooling system

Distillation of Crude Silane. The crude silane mixture (for composition, see page 5) is separated into individual silanes in columns with very high separating capacity, connected in series. Since the organic chlorosilanes are building blocks for silicones, they must fulfill high purity requirements. Even a small amount of tri- or monofunctional silanes in the dichlorodimethylsilane can bring about chain branching ($MeSiCl_3$) or chain termination (Me_3SiCl). The high purity required for Me_2SiCl_2 is achieved by distillation of the Me_2SiCl_2 obtained in the fractional distillation of the crude silane mixture.

Corrosion Problems. Steel is the preferred construction material for the direct process plant. Because methylchlorosilanes, particularly CH_3Cl, react with zinc, tin, magnesium, and aluminum at elevated temperature, these metals

must not be used as alloy components. In some parts of the plant, enamel or Teflon must also be used.

Direct Synthesis with Halogen-Free Compounds. Many experiments have been described on the application of direct synthesis to halogen-free compounds. None of these routes have become important economically. A summary can be found in [46]. Treatment of silicon with dimethyl ether would be particularly interesting because it should give halogen-free methoxymethylsilanes. Such compounds could also serve as starting materials for the production of silicones. This would avoid the corrosion problems caused by HCl in the methods used up till now. Although a reaction between silicon and dimethyl ether can be achieved [47], the drastic reaction conditions required and the low yields of useful products make this route unlikely to become an economical alternative to conventional direct synthesis.

2.2. Grignard Synthesis

The Grignard synthesis of organosilanes, in particular organohalosilanes, was introduced by DILTHEY and KIPPING [19]. It still attracts much interest because of its universal preparative possibilities. For the synthesis of special silanes by the introduction of certain saturated or unsaturated hydrocarbon groups, this is frequently the best synthetic route.

Silanes with halogen or alkoxy groups can be used as starting materials. For example, $SiCl_4$ and $HSiCl_3$ can be treated with methyl Grignard reagents to give the silanes known from the direct synthesis (e.g., Eq. 9):

$$HSiCl_3 + RMgX \longrightarrow MgXCl + RSiHCl_2 + R_2SiHCl + R_3SiH \quad (9)$$

Mono-, di-, and trichlorosilanes can act as starting materials for mixed alkyl–arylchlorosilanes:

$$RSiCl_3 + ArMgX \longrightarrow MgXCl + RSiArCl_2 + RSiAr_2Cl + RSiAr_3 \quad (10)$$

Ar = Aryl

Ethers are the most frequently used solvents in Grignard synthesis (diethyl ether, dibutyl ether, THF, ethylene glycol ethers). The reactivity is particularly high in THF. In this solvent, vinyl groups have been introduced for the first time by using vinylmagnesium bromide [48], and Si–H groups can be substituted with alkyl groups [49].

The first step in Grignard synthesis is preparation of the Grignard solution. In some cases it can be prepared in situ in the presence of the halo- or alkoxysilane. This route also offers the possibility of a continuous Grignard synthesis [50]. The nature of the halogen or alkoxy group bonded to silicon, the number and nature of the organic groups already present in the starting silicon compound, and the size of the group to be introduced are some important factors for the result of the Grignard synthesis. Steric hindrance can make reactions proceed sluggishly or not at all, but it can also allow the formation of a desired, partially substituted product in high yield. Without steric hindrance the reaction is generally complete only after all halogens have been replaced. If fluorosilanes are used, particularly high degrees of substitution with bulky organic groups can be achieved because of the small size of the fluorine atom.

In some cases the reaction can be controlled by addition of catalysts. The reaction of dichlorodiphenylsilane [*80-10-4*] with *tert*-butyl Grignard in THF in the presence of CuCN or CuSCN gives *tert*-butylchlorodiphenylsilane [*58479-61-1*] in 75 % yield (Eq. 11); without catalyst, no reaction occurs [51].

$$tert\text{-}BuMgX + Ph_2SiCl_2 \xrightarrow{\text{Cat.}} MgXCl + tert\text{-}BuPh_2SiCl \quad (11)$$

Cat.: e.g., CuCN, CuSCN, Me_3SiCN

Even in the absence of steric hindrance, the yield of partially substituted intermediates can be increased by using an appropriate stoichiometry of starting materials. Generally, however, separation of the resulting mixtures is uneconomical.

Silicon-bonded alkoxy groups react with Grignard reagents more slowly than halogens; the reactions are thus easier to control. For example, diisobutyldimethoxysilane can be synthesized from tetramethoxysilane and isobutyl Grignard in 95 % yield and > 97 % purity [52].

Disadvantages of Grignard syntheses are the high consumption of anhydrous, mostly volatile,

and readily flammable solvents and the formation of large amounts of salts. They are also often accompanied by side reactions. Because of this they are used industrially only in exceptional cases (e.g., for the production of organosilicon compounds of particularly high value).

2.3. Syntheses with Alkali Metals

The reaction of halosilanes with organic compounds of alkali metals or in situ with the reaction products of haloalkanes and alkali metals is an alternative or a supplement to the Grignard synthesis and is also usually carried out only on a laboratory scale:

$$RLi + ClSi{\equiv} \longrightarrow RSi{\equiv} + LiCl \quad (12)$$

$$RCl + ClSi{\equiv} + 2\,Na \longrightarrow RSi{\equiv} + 2\,NaCl \quad (13)$$

Because of the high reactivity of organometallic compounds, they can also attack solvents. However, their advantage is that highly sterically demanding organic groups can often be introduced when this is not possible with a Grignard reagent [53].

With the smaller methyl or ethyl groups, all halogens are generally replaced. Even Si−OR and Si−H groups can react with organolithium compounds [54, 55].

Organozinc and organoaluminum compounds can also be used for alkylations [56].

2.4. Addition Reactions (Hydrosilylation)

Silanes and siloxanes that contain Si-bonded hydrogens can add to compounds with C−C multiple bonds (Eqs. 14 and 15). On addition to alkynes, alkene derivatives are formed initially, to which a second molecule of the Si−H compound can be added, provided no steric hindrance occurs.

$$\equiv SiH + R_2C{=}CR_2 \longrightarrow \equiv SiCR_2CR_2H \quad (14)$$

$$\equiv SiH + RC{\equiv}CR \longrightarrow \equiv SiCR{=}CRH \quad (15)$$

Hydrosilylation is used industrially for synthesizing alkylsilanes and functional silanes, cross-linking silicone polymers, binding silicone polymers to organic polymers, and removing impurities that contain Si−H groups from silane fractions of the direct synthesis.

Two different hydrosilylation routes are possible. Both make use of the high enthalpy of formation, estimated to be 160 kJ/mol for the addition of an Si−H group to a simple alkene, and the fact that the Si−H bond is readily activated. The first method developed is based on a chain mechanism involving silyl radicals [23]:

$$HSiCl_3 \longrightarrow H^{\cdot} + {}^{\cdot}SiCl_3 \quad (16)$$

$${}^{\cdot}SiCl_3 + CH_2{=}CHCH_3 \longrightarrow Cl_3SiCH_2\dot{C}HCH_3 \quad (17)$$

$$Cl_3SiCH_2\dot{C}HCH_3 + HSiCl_3 \longrightarrow Cl_3SiCH_2CH_2CH_3 + {}^{\cdot}SiCl_3 \quad (18)$$

Silyl radicals can be generated thermally, by decomposition of radical initiators (e.g., acyl peroxides, azonitriles), by UV light, or by γ-radiation. With this method a large number of side products can be formed by decomposition of the initiators and polymerization of the alkene components. It is used industrially only in exceptional cases.

The route used almost exclusively in industry is the transition-metal-catalyzed addition of Si−H groups to multiple-bond systems.

In 1953, some supported transition metals were found to be very effective hydrosilylation catalysts. In particular, Pt – active charcoal is an highly active catalyst for the reaction of $HSiCl_3$ with acetylene, ethylene, butadiene, allyl chloride and $H_2C{=}CF_2$ at ca. 130 °C [57]. In 1957, Speier reported that chloroplatinic acid, $H_2PtCl_6 \cdot 6\,H_2O$, and its salts are catalysts that allow very rapid addition of a wide range of silanes to various alkenes, sometimes even below room temperature. This provided the possibility of hydrosilylating complex organic molecules. A summary of this work can be found in [58].

Mechanism. In the transition-metal-catalyzed addition reaction the ability of the transition metal to change its coordination number with a simultaneous change in oxidation state is exploited. This is shown in the example of platinum, where the reaction takes place at particularly active atoms on the metal surface or in the coordination sphere of the dissolved

complex (Eq. 19). The Si—H bond adds oxidatively to platinum, and a π-bond to the olefin is formed.

(19)

Both steps are reversible. The reaction is completed by addition of hydrogen to the π-bonded molecule, which is also reversible. This is followed by reductive elimination of the silicon group with the σ-bonded organic ligand. When the final product is liberated the platinum catalyst is reformed and can reenter the cycle [59]. This mechanism explains most phenomena observed in the reaction. It is supported by the fact that in some cases, the intermediates can be characterized unambiguously. A more recent example is described in [60]. Colloidal solutions of platinum and other metals are also particularly active catalysts (see [61, 62], and references cited therein).

In general the β-addition product is preferentially formed in hydrosilylation:

(20)

However, by using special catalysts (e.g., Rh or Pd compounds), the α-addition product can be isolated as the main component [63].

Olefins with terminal double bonds generally react faster than inner olefins. With the latter the terminal addition product is also formed because isomerization of the olefin occurs in the reversible first reaction step [64]. Silanes vary in reactivity depending on the nature of the substituents. Chlorosilanes are the most reactive, followed by alkoxysilanes; purely organic silanes and siloxanes frequently react sluggishly.

Catalysts. In industry, platinum catalysts such as Pt – activated charcoal, Pt – silica gel, $H_2PtCl_6 \cdot 6\,H_2O$ – vinylsiloxane (Karstedt solution), $H_2PtCl_6 \cdot 6\,H_2O$ (Speier catalyst), and Pt olefin complexes are the most widely used. Palladium and rhodium compounds are also frequently used. For special applications a large number of catalysts based on other metals (main-group, transition, and rare-earth metals) have been developed [65]. In homogeneous catalysis the usual platinum concentrations are in the milligram-per-kilogram range, based on the silane used.

Hydrosilylation of Other Multiple-Bond Systems. Other multiple-bond systems such as

can be hydrosilylated catalytically. These reactions and hydrosilylation in the presence of carbon monoxide are not described here; details can be found in [11, 58, 65].

2.5. Substitution Reactions of Si—H Bonds

Organic groups can also be bonded to silicon by substitution of Si—H bonds. The syntheses of $PhSiCl_3$ [*98-13-5*] (Eq. 21, an alternative to the direct synthesis) and $MePhSiCl_2$ [*149-74-6*] (Eq. 22) are important industrially.

$$HSiCl_3 + C_6H_5Cl \xrightarrow{\text{ca. } 500\,^\circ\text{C}} C_6H_5SiCl_3 + HCl \qquad (21)$$

$$MeHSiCl_2 + C_6H_5Cl \xrightarrow{\text{ca. } 500\,^\circ\text{C}} C_6H_5MeSiCl_2 + HCl \qquad (22)$$

The use of Friedel – Crafts catalysts, proposed earlier, is unnecessary because they favor side reactions and decomposition. The yields are 60 – 70 %; $SiCl_4$ or $MeSiCl_3$ and benzene are formed as side products [66].

Trichlorovinylsilane [*75-94-5*] can be obtained similarly from vinyl chloride and trichlorosilane [67].

In the presence of BCl_3 or $AlCl_3$, hydrocarbons can also undergo this type of reaction with the elimination of H_2 (Eq. 23).

$$\equiv SiH + RH \longrightarrow \equiv SiR + H_2 \qquad (23)$$

A variant is shown in Equation (24):

$$\equiv\mathrm{SiH} + \mathrm{ArH} + \mathrm{Cl_2} \longrightarrow \equiv\mathrm{SiAr} + 2\,\mathrm{HCl} \qquad (24)$$

For the mechanism of this reaction, see [68].

Other substitution reactions of Si−H bonds and other Si−X bonds are discussed in Chapter 3.

2.6. Coproportionation and Disproportionation

Co- and disproportionations are used for the conversion of silanes with undesired degrees of substitution into industrially utilizable products (Eq. 25):

$$\mathrm{SiR_4} + \mathrm{SiR_4^1} \underset{\text{Disproportionation}}{\overset{\text{Coproportionation}}{\rightleftharpoons}} 2\,\mathrm{Si(R, R^1)_4} \qquad (25)$$

The reaction is accelerated by Friedel – Crafts catalysts ($AlCl_3$, Na_3AlCl_6, CuCl), organic amines, and sodium alkoxides in the case of alkoxysilanes.

There are few limitations as to the nature of the substituents that can be exchanged because alkyl and aryl groups, alkoxy groups, halogen, and hydrogen atoms are all exchangeable [69, 70]. A simple example is the coproportionation shown in Equation (26), which proceeds at moderate temperature.

$$\mathrm{MeSiCl_3} + \mathrm{Me_3SiCl} \xrightarrow{\text{Cat.}} 2\,\mathrm{Me_2SiCl_2} \qquad (26)$$

In practice, to increase the yield of Me_2SiCl_2 high- and low-methyl fractions from the direct synthesis are coproportionated catalytically in a similar way [71].

3. Silicon-Functional Organosilicon Compounds

This chapter deals mainly with organosilicon compounds of the general formula R_nSiX_{4-n} having at least one Si−X group that can be cleaved hydrolytically (X = halogen, OR^1, NR_2^1; R, R^1 = H, alkyl, aryl). Fundamental aspects of these silanes are described in [8, 10]. An overview of the data for important individual compounds is given in [72].

Reactivity. Equation (27) describes the protolysis of silanes with cleavable groups X [73].

$$\mathrm{R}_n\mathrm{SiX}_{4-n} + (4-n)\,\mathrm{HY} \longrightarrow \mathrm{R}_n\mathrm{SiY}_{4-n} + (4-n)\,\mathrm{HX} \qquad (27)$$

Industrially this is carried out with many reactants HY and has led to various industrial processes, depending on the nature and number of R groups, and the nature of the leaving group X and the nucleophile Y (Scheme 1, with X = Cl). Some syntheses also exploit the interconversion of the silicon-functional derivatives [e.g., shifting the equilibrium by removing volatile components through distillation (Eqs. 28 and 29)].

Scheme 1. Industrially important reactions of organochlorosilanes R_nSiCl_{4-n} with nucleophiles Y, according to Eq. (27) (protolysis)

$$\equiv SiNHR + HON{=}CR^1R^2 \xrightarrow{Cat.} \equiv SiON{=}CR^1R^2 + H_2NR \quad (28)$$

$$\equiv SiOR^1 + (MeCO)_2O \xrightarrow{Cat.} \equiv SiOCOMe + MeCOOR^1 \quad (29)$$

If silane compounds are reacted with one another, the thermodynamic equilibrium (as opposed to a purely statistical distribution) can be shifted in the direction of a specific component (Eqs. 30 and 31).

$$2\,RSi(NHR^1)_3 + RSiCl_3 \xrightarrow{Cat.} 3\,RSiCl(NHR^1)_2 \quad (30)$$

$$RR^1Si(OR^2)_2 + RR^1SiCl_2 \xrightarrow{Cat.} 2\,RR^1Si(OR^2)Cl \quad (31)$$

This can be attributed to differences in the free enthalpy of reaction, which has been calculated for many combinations [74]. Other metal atoms can also be incorporated in such reactions:

$$TiCl_4 + n\,Me_3SiOR^1 \longrightarrow Cl_{4-n}\,Ti(OR^1)_n + n\,Me_3SiCl \quad (32)$$

$n = 1-3$

3.1. Halo- and Pseudohalosilanes

Chlorosilanes are produced by the processes described in Chapter 2. They are generally liquids and are thermally quite stable. Their overall high reactivity in protolytic processes is intermediate in the series SiF << SiCl < SiBr < SiI and decreases with increasing substitution at silicon in the order $SiCl_4 > RSiCl_3 > R_2SiCl_2 > R_3SiCl$ and with increasing steric hindrance in the group R in the series H, CH_3, C_2H_5, $CH(CH_3)_2$, $C(CH_3)_3$.

The interest in organic synthesis has concentrated for some time on trialkylsilyl derivatives with sterically demanding R groups and particular leaving groups X. The highly reactive [75], light-sensitive iodotrimethylsilane is being used increasingly in industry. It is produced by in situ cleavage of hexamethyldisilane (see Section 5.2) in solution with elemental iodine. The crystalline, volatile *tert*-butylchlorodimethylsilane (*mp* 89 °C, *bp* 125 °C) also has specific applications. Besides its synthesis from *tert*-butyllithium and dichlorodimethylsilane, new routes have also been proposed, analogous to Equation (11). The sterically demanding chlorodimethylhexylsilane [*67373-56-2*] is formed from chlorodimethylsilane and tetramethylethylene over aluminum chloride [76] according to Equation (14). For the uses of these compounds and information on pseudohalosilanes Me_3SiX (e.g., X = CN/NC, NCO, NCS, N_3) the literature cited in Section 6.1 should be consulted.

3.2. Alkoxy- and Aryloxysilanes

The alkoxylation of chlorosilanes to give alkoxysilanes (Eq. 33) is of major industrial importance.

$$R_nSiCl_{4-n} + (4-n)\,HOR^1 \longrightarrow R_nSi(OR^1)_{4-n} + (4-n)\,HCl \quad (33)$$

R = H, alkyl, aryl; also organofunctional; R^1 = Me, Et, etc.

Alkoxysilanes are preferred because of their advantages in further use. They do not produce any hydrogen chloride (TLV 7.5 mg/m^3; in comparison, methanol = 262 mg/m^3, ethanol = 1880 mg/m^3). Acid-sensitive substances (e.g., acetone) or basic catalysts can be used in processing. Higher boiling points and flash points compared to chloro compounds (Table 3) permit the use of open apparatus under certain circumstances, and corrosion-resistant materials need not be employed. Alkoxysilanes hydrolyze more slowly and in a more controlled manner than chlorosilanes and allow access to silanols [77], defined silicone resins, or sol – gel precursors (→ Inorganic Polymers, Chap. 9.). Mixed condensations of alkoxysilanes give better yields of the target product [78] (Eq. 34), compared to chlorosilanes.

$$RSiCl_3 + Me_3SiCl \xrightarrow[\text{2) Water}]{\text{1) Isopropanol}} \underset{94\,\%}{RSi(OSiMe_3)_3} \quad (34)$$

$R = CH_2CH_2CH_2Cl$

Alkoxysilanes also offer advantages in the Grignard synthesis (Section 2.2). Coupling with

sodium and organic halogen compounds proceeds similarly [79].

Significant uses of silanes [e.g., as coupling agents or for polyethylene cross-linking (Section 6)] were able to be developed to their current major importance only with the introduction of neutral alkoxy compounds.

Synthesis. The formation of alkoxysilanes according to Equation (33) is often associated with undesired side reactions, such as elimination of haloalkanes (Eq. 8) or olefins, resulting in the simultaneous formation of siloxanes. The reactions proceed more cleanly if the hydrogen chloride liberated is removed by (tertiary) amines. The additional costs of these bases and the necessary solvents and the moderate yields led to the use of processes that do not require neutralization and allow recycling of the large quantities of HCl liberated. The best industrial process is continuous, solvent-free production in a corrosion-resistant distillation column [80]. Chlorosilane, prereacted with alcohol, is fed into the upper third of the column countercurrent to the alcohol vapor coming up from the circulation evaporator at the bottom. HCl gas with a low silane content escapes via the condenser. If pure silanes are used, the quality of the alkoxysilane removed from the base of the column depends on the boiling point and water content of the alcohol. It does not generally need to be distilled. Usually alcohol-sensitive groups such as SiH, $SiCH_2CH_2Cl$, or $SiCH_2CH_2CN$ remain unreacted, since the alcohol can be used in strictly stoichiometric quantities. The action of excess alcohol on SiH groups, especially in the presence of bases, leads to loss of hydrogen according to Equation (35), often with a dangerous pressure buildup.

$$\equiv SiH + HOR^1 \xrightarrow{Cat.} \equiv SiOR^1 + H_2 \qquad (35)$$
$$R^1 = \text{Alkyl (or also H)}$$

In the absence of free alcohol, $HSi(OEt)_3$ [*998-30-1*] and potassium ethoxide form the synthetically interesting pentacoordinate compound $[HSi(OEt)_4]K$ [81]. Reactions of the type shown in Equation (35) can also be used for the synthesis of silanols or alkoxysilanes (e.g., by using Pd catalysts; see also Section 3.6).

The reaction of simple alcohols with a hydrolyzable group other than SiCl is used only in exceptional cases for economic reasons. Silyl ethers of higher-boiling alcohols or phenols are formed from methoxy- or ethoxysilanes, the best results being obtained with alkaline catalysts (e.g., alkoxides) and by distillation of the volatile alcohol. The quite selective formation of diethoxymethylsilane [*2031-62-1*], which is difficult to obtain by the above route (see Eq. 33), from oligomeric methylhydrogensiloxane [82] (Eq. 36) is noteworthy:

$$\left[-\overset{H}{\underset{Me}{Si}}O-\right]_n + n\,MeSi(OEt)_3 \xrightarrow{AlX_3} \left[-\overset{OEt}{\underset{Me}{Si}}O-\right]_n + n\,MeSiH(OEt)_2 \qquad (36)$$

Alkoxytrimethylsilanes are readily formed from the highly reactive nitrogen derivatives (see Section 3.5). Ethers of *tert*-butanol are obtained from the chlorosilane with amines or alcoholates, and phenol ethers are obtained without the addition of HCl-binding reagents. The phenoxysilanes have particularly high thermal sta-

bility: $Si(OC_6H_5)_4$ [*1174-72-7*] boils without decomposition at ca. 405 °C.

The most important reaction of the alkoxysilanes is with water. While earlier work was concerned with preparative aspects, more recent investigations on hydrolytic behavior have focussed on the kinetics in dilute, homogeneous, predominantly solvent-free solutions [73, 83–86]. Alkoxysilanes are generally insoluble or sparingly soluble in water. They undergo loss of alcohol (Eq. 37) to give reactive silanols. The first step is rate limiting.

$$R_nSi(OR^1)_{4-n} + H_2O \xrightarrow{\text{Cat.}} R_nSi(OR^1)_{3-n}(OH) + R^1OH$$
$$\downarrow + H_2O \qquad (37)$$
$$R_nSi(OR^1)_{2-n}(OH)_2 + R^1OH$$
$$\downarrow \text{etc.}$$

The silanols are solvated by water because of their higher polarity and their capacity to form hydrogen bonds, sometimes resulting in complete miscibility. Condensation to give siloxanes, which are generally insoluble, occurs parallel to hydrolysis (Eq. 38).

$$2 \equiv SiOH \longrightarrow \equiv SiOSi \equiv + H_2O \quad (38)$$

Compared with halogens the alkoxy group is a poorer leaving group. Its reactivity toward nucleophiles is limited and decreases roughly in the order $OR^1 = OCH_3 > OC_2H_5 > OCH(CH_3)_2 > OC_6H_5 > OC(CH_3)_3$. The relationships among pH, rate of hydrolysis, and stability shown for 3-glycidoxypropyltrimethoxysilane [*2530-83-8*] (Fig. 2) hold approximately for the formation and condensation of all silanols. In general, precise pH control is important for the reproducibility of the reaction and the quality of the hydrolysis product. Even traces of chlorinated hydrocarbons, formed during the alkoxylation of industrial methylchlorosilanes from olefinic side products of Rochow silanes (Section 2.1), can disturb the reaction by uncontrolled liberation of HCl [87]. The stability of the silanols $R_nSi(OH)_{4-n}$ toward condensation increases with increasing n. Unlike the quite insensitive phenylsilanols, such as $Ph_2Si(OH)_2$ [*947-42-2*], compounds with the general formula R_3SiOH condense in the presence of traces of acid with the elimination of water to give disiloxanes. Under neutral conditions they can be stored almost indefinitely. Steric hindrance in the R group also leads to stabilization. Because of hydrogen bonding, Me_3SiOH [*1066-40-6*] (M_r 90) boils at ca. 100 °C, as does its "dimer" $Me_3SiOSiMe_3$ (M_r 162). The unstable dimethylsilanediol [*1066-42-8*] [77] may be an intermediate in the hydrolysis of dichlorodimethylsilane to form silicone fluids. In addition to linear polydimethylsiloxanes (PDMSs) the primary hydrolysate contains cyclic compounds $(Me_2SiO)_n$ ($n \geq 3$; for CAS numbers and physical properties, see Table 4). The high ring strain of $(Me_2SiO)_3$ not only allows facile ring opening to give siloxane polymers (Eq. 39) but also reaction with silanols to give ambivalent siloxanes [88] (Eq. 40).

Figure 2. pH-dependent behavior of 3-glycidoxypropyltrimethoxysilane in aqueous solution (ca. 0.25 mol/L) [83]

$$n\,[SiMe_2O]_3 \xrightarrow{\text{Cat. or heat}} [SiMe_2O]_{3n} \qquad (39)$$
$$n\,[SiMe_2O]_3 + RMe_2SiOH \xrightarrow{\text{Cat.}} R[Me_2SiO]_{3n+1}H \qquad (40)$$

R = (Functional) alkyl group

Cyclic siloxanes react particularly readily with chlorosilanes such as $MeRSiCl_2$ (R = H, Me, $CH{=}CH_2$) to form linear, short-chain, α,ω-halogenated siloxanes [89], which can be worked up hydrolytically to yield polymers.

Table 4. Industrially important methyloligosiloxanes

Structure *	CAS no.	*mp*, °C	*bp*, °C

* $V = CH_2{=}CH$.
** Mixture of positional isomers.

Siloxane cleavage also occurs with highly reactive silanols formed in situ from chloro- or alkoxysilanes, water, and a catalyst [90], often selectively (silanolysis, Eq. 41; X = Cl, OR^1).

$$2\ RSiX_3 + 3\ HMe_2SiOSiMe_2H \xrightarrow[H^+]{3\ H_2O} 2\ RSi(OSiMe_2H)_3 + 6\ HX \qquad (41)$$

The reactivity of well-defined oligosiloxanes is reported in [91].

Water-soluble alkylsilanetriols can be stabilized only for a limited period in dilute solution under weakly acidic conditions. On warming, aeration of the solvent, or increasing the pH, they condense to resinous, generally water-insoluble polymers.

In strongly alkaline media, alkali-metal siliconates **1** are formed from $RSi(OR^1)_3$ (Eq. 42).

These are widely used to render mineral substrates hydrophobic. They react with atmospheric carbon dioxide to form insoluble, water-repellent methylsilicone resin, which is permeable to water vapor. It is used for impregnating mineral construction materials such as roofing tiles, or for protection against rising damp, particularly in old walls with low alkali content. More recently, silicone microemulsions have been used successfully (see Section 6.8).

A special category of alkoxysilanes is the silenol ethers, which can be obtained according to Equation (43) [92].

$$CH_3SiCl_3 + 3\ O{=}\underset{\underset{R^2}{|}}{C}{-}CH_2R^1 + 3\ B \longrightarrow CH_3Si(O{-}\underset{\underset{R^2}{|}}{C}{=}CHR^1)_3 + 3\ B\cdot HCl \qquad (43)$$

Moisture converts the enolized leaving group back into the starting neutral ketone [e.g., acetone (R^1 = H, R^2 = Me) or 5,5-dimethyl-1,3- cyclohexanedione (see Section 6.3)].

Esters of orthosilicic acid, $Si(OR^1)_4$, and their lower condensation stages are not organosilanes in the strictest sense. However, because of their industrial importance they are covered here. Unlike organo(organoxy)silanes, tetraalkoxysilanes are synthesized directly from silicon [93] or suitable natural silicates [94] and alcohols. Many side products are formed in this reaction, so that the overall energetic advantages of this direct synthetic route are offset by an uneconomical workup. Therefore products from the reaction of $SiCl_4$ with ethanol and water, which have a calculated SiO_2 content of 40 wt %, are used in practice [95]. These so-called ethyl silicates 40 [*26352-16-9*] are mixtures of linear, branched, and cyclic ethoxysiloxanes, which are stable on storage; their viscosity is ca. 4 mm^2/s. Unlike analogous condensation products of the toxic tetramethyl silicate, the cheap ethoxy compounds are used in large quantities. Water or atmospheric moisture causes loss of ethanol to give a strongly adhering silicic acid binding agent. Hydrolysis and cross-linking can be accelerated by catalysts. Examples of uses are:

1) Cross-linking of silicone rubber (see Table 6).
2) Inhibition of fiber pilling on polyester fabrics [as a mixture with alkoxyphosphorus compounds; 2-(diethylphosphono)-ethyltriethoxysilane has been used as an alternative, see Section 4.6].
3) Consolidation of weathered sandstone for renovation of buildings (catalyst alkylacyltin compounds) [96], with retention of the open-pored character of the stone.
4) Protection of metallic construction components (bridges, containers, ships, pipelines): finely divided zinc pigments and other additives form impermeable coatings (cold galvanization) with silicic acid on steel, which protect against water and chloride ions and are resistant up to 420 °C. Even if the layer is damaged, the protective action is retained, since a local element is formed with zinc as the anode [97].
5) Making molds for precision casting: In many work cycles thin layers of ethyl silicate and fireproof pigments are deposited on top of each other on wax patterns and hardened in air or an ammonia atmosphere. After melting of the wax and firing at ca. 1000 °C the metal is cast into the porous mold.

3.3. Acyloxysilanes

Acyloxysilanes, $R_nSi(OCOR^1)_{4-n}$, are less readily formed than the alkoxy compounds. Acetoxysilanes ($R^1 = Me$) are very important industrially as cross-linking agents in one-component silicone sealants (RTV 1 systems; see → Silicones, Chap. 4.4.3.; and Section 6.3). They can only be produced economically from the reactive chlorosilanes:

$$RSiCl_3 + 3\,Ac_2O \longrightarrow RSi(OAc)_3 + 3\,AcCl \quad (44)$$

$$RSiCl_3 + 3\,HOAc \longrightarrow RSi(OAc)_3 + 3\,HCl \quad (45)$$

$$R = CH_3, C_2H_5, HC{=}CH_2;\ Ac = COCH_3$$

The first, older variant (Eq. 44) requires removal of acetyl chloride by distillation. Heating in the presence of traces of catalytically active metals can lead to reformation of acetic anhydride and oligomerization (Eq. 46).

$$2 \equiv SiOAc \longrightarrow \equiv SiOSi\equiv + Ac_2O \quad (46)$$

Continuous countercurrent reaction with acetic acid is more suitable (Eq. 45) [98]. The products are practically free of chloride, acid, and anhydride, and yields are close to 100 %. The compounds, known as acetic acid hardeners, are spontaneously hydrolyzable, corrosive, high-boiling liquids with melting points between 5 and 45 °C.

3.4. Oximino- and Aminoxysilanes

The trend toward RTV 1 systems, whose cross-linking agents eliminate neutral products, has made the long-known oxime and aminoxy cross-linking agents even more important industrially. Intensive work has been carried out on the production of alkyloximinosilanes; the oximino group (Ox) is generaly $-ON{=}C(CH_3)C_2H_5$ [99]. The best process is the reaction shown in Equation (47) [100].

$$MeSiCl_3 + 6\,HOx \xrightarrow[<60\,^\circ C]{\text{Solvent}} MeSi(Ox)_3 + 3\,HOx \cdot HCl \quad (47)$$

The amphoteric 2-butanone oxime acts as both a reactant and a "base". With hydrogen chloride it forms a liquid, readily separable phase that can be reacted with alkali to give 2-butanone oxime again. Careful dosage and monitoring lower the danger of vigorous decomposition of the acidic oxime hydrochloride.

Aminoxysilanes, $R_nSi(ONR^1R^2)_{4-n}$, are formed by reaction of hydroxylamines with alkylchlorosilanes, with removal of the liberated hydrogen chloride by bases [101]; another possible route is shown in Equation 53.

3.5. Aminosilanes, Amidosilanes, and Silazanes

(Alkylamino)alkylsilanes. Because of the high affinity of amines for HCl the industrial synthesis according to Equation (48) requires an excess of base. Triethylamine (A) can be used as co-base and solvent [102]. The granular, crystalline, readily separable hydrochloride formed can be worked up for reuse.

$$\equiv SiCl + H_2NR^1 + A \longrightarrow \underset{\text{Silylamine or (mono-)silazane}}{\equiv SiNHR^1} + A \cdot HCl \qquad (48)$$

When carbon dioxide is passed through, carbamatosilanes $\equiv SiOCONHR^1$ are formed from silylamines [103].

Amidosilanes. The amidosilanes $R_nSi-[NR^1C(O)R^2]_{4-n}$ ($R, R^1 = Me$; $R^2 = Me$ or $C_6H_5CH_2$), which are useful neutral cross-linking agents, are formed from chlorosilanes and organic amides by using strongly alkaline HCl scavengers (e.g., sodium metal or methoxide) or from Si–H compounds [104].

The silicon-monofunctional derivatives of urea and acetamide (see Table 5), used in large quantities for the synthesis of pharmaceuticals, also belong to this group of substances. *N,N′*-Bis(trimethylsilyl)urea (BSU) is produced industrially in quantitative yield from hexamethyldisilazane (HMDS) and urea, with, for example, a catalytic quantity of an ammonium salt or an organic sulfonamide [105] (Eq. 49).

$$(Me_3Si)_2NH + H_2NCONH_2 \xrightarrow[120\,^\circ C]{Cat.} (Me_3SiNH)_2CO + NH_3 \qquad (49)$$

The *N,O*-bis(trimethylsilyl)acetamides are among the most powerful trimethylsilyl-transfer agents. Production involves the conversion of acetamide into the liquid BSA by means of Me_3SiCl – trialkylamine via the solid monosilyl derivative (MSA) [106] (Eq. 50).

(50)

On heating in the presence of Fe ions, for example, bis(trimethylsilyl)amides decompose to hexamethyldisiloxane and the corresponding nitrile, as indicated by the dashed lines in Equation (50).

Disilazanes. Many chlorosilanes react with ammonia to give not stable, simple silylamines $\equiv SiNH_2$, but disubstitution products with the SiNHSi building block. Hexamethyldisilazane has achieved major industrial importance. The exothermic reaction according to Equation (51) can be carried out in solvents such as hexane, toluene, or isododecane, but is best performed in warm HMDS itself [107].

$$2\,Me_3SiCl + 3\,NH_3 \longrightarrow (Me_3Si)_2NH + 2\,NH_4Cl \qquad (51)$$

The latter variant leads to the formation of coarse-grained ammonium chloride, which can be readily stirred and filtered and gives better turnover and yield. The suggestion has been made that the salt be separated by treatment with water. HMDS forms strong hydrogen bonds and is only weakly basic. Alkali and alkaline-earth metals form salts with it, e.g., $LiN(SiMe_3)_2$ [*4039-32-1*].

3.6. Hydrogensilanes

Organohydrogensilanes (H-silanes) are obtained by the general synthetic methods described in Chapter 2. The cheapest raw material for Si–H compounds, trichlorosilane [*10025-78-2*], is produced from silicon and hydrogen chloride (→ Silicon Compounds, Inorganic, Chap. 2.1.1.). An Si–H synthesis from halosilane and metal hydride can only be considered for special, high-value sil(ox)anes [108]. Cleavage of Si–H bonds (and Si–Ph) is effected by halogens, giving halogen derivatives. H-Substitution also takes place on protolysis (e.g., Eq. 35). Other reactions of Si–H silanes involving loss of hydrogen are summarized in [109].

Many of the reactions shown in Scheme 1 can be carried out with retention of the Si–H group. Insertion into Si–H bonds occurs on hydrosilylation (Section 2.4). In this way, the compounds $R_nSiH(OR^1)_{3-n}$, which can be produced from the corresponding chlorosilanes and alcohols, can be converted into functional alkoxyalkylsilanes (see Chapter 4). With amine or metal catalysts the alkoxy H-silanes sometimes undergo H-redistribution. In the absence of SiC-bonded groups, monosilane SiH_4 [*7803-62-5*], which is spontaneously flammable in air, can be formed [110]. The methylhydrogensiloxanes, which are used widely in industry, can react spontaneously with traces of alkali [111] according to Equation (52), to give gaseous methylsilane, $MeSiH_3$ [*992-94-9*].

$$3\left[\text{MeSi(H)O}\right] \xrightarrow{\text{Cat.}} \text{MeSiH}_3\text{(g)} + 2\left[\text{MeSiO}_{3/2}\right] \quad (52)$$

Siloxanes with the structural elements **2**, **3**, or **4**, formed according to Equation (53), are effective condensation cross-linking agents.

$$\left[\text{MeSi(H)O}\right] + \text{HY} \xrightarrow{\text{Cat.}} \left[\begin{array}{c}\text{MeSiO}\\ |\\ \text{Y}\end{array}\right] + \text{H}_2 \quad (53)$$

2 – 4

2: $Y = NR^1C(O)R^2$ [104];

3: $Y = OCH_2CH_2NR^1_2$ [112];

4: $Y = ONR^2_2$ [113]; R^1 = e. g., Me; R^2 = e. g., Me , Et

4. Organofunctional Organosilicon Compounds

Compared with the compounds described in Chapter 3, which react exclusively at the labile substituent X on the silicon, in this chapter derivatives with functionalized organic groups R^1 are considered. These silanes can be described by the general formula $X_nR_{3-n}Si{-}R^1{-}Y$, except for the alkenyl-substituted compounds. The alkyl substituents R and the leaving groups X correspond to those in Chapter 3. The Y groups, which are generally attached by stable bonds, are decisive for the activity of this class of compounds. These organic functional groups are used to bond quite different organic polymers to one another and to inorganic surfaces via siloxane bridges. The Y group generally participates itself in chemical bonding (e.g., in coupling agents, cross-linking agents) or at least increases the compatibility of different materials and surfaces.

The industrial development of this class of substances is closely associated with that of hydrosilylation. Vinylsilanes were first used, followed by aminopropyl- and mercaptosilanes [114]. In 1963 the methacrylic function, and later the epoxy and cationic styrene derivatives, came on the market.

4.1. Vinyl and Other Alkenyl Compounds

Industrial use of organofunctional silanes began in the early 1950s with the development of vinylsilanes and their reinforcing effect in glass-fiber – polyester plastics. Alkenyl compounds still dominate as strengthening additives in polymer applications and, in particular, as reactive components in many silicone formulations.

Vinylsilanes are produced on a large scale mainly by continuous processes. The preferred route is catalytic addition of hydrogen-bearing chlorosilanes to acetylene.

$$\text{HC}{\equiv}\text{CH} + \text{H}\overset{\overset{\text{X}}{|}}{\text{Si}}\text{RR}^1 \xrightarrow{\text{Pt}}$$

X = Cl

$$\text{H}_2\text{C}{=}\text{CH}{-}\overset{\overset{\text{X}}{|}}{\text{Si}}\text{RR}^1 + \text{R}^1\overset{\overset{\text{X}}{|}}{\text{R}}\text{Si}\text{CH}_2\text{CH}_2\overset{\overset{\text{X}}{|}}{\text{Si}}\text{RR}^1 \quad (54)$$

In 1953 the use of platinum on solid carriers for this reaction was patented [57]. For example, trichlorosilane and acetylene react at ca. 130 °C in a tubular reactor to give a product mixture with 70 % $CH_2{=}CHSiCl_3$ and 19 % of the diadduct after a few minutes. Formation of $Cl_3SiCH_2CH_2SiCl_3$, derivatives of which are used to a limited extent as "bridging hardeners," can be suppressed by using a large acetylene excess and short residence time. Since heterogeneous catalysts such as Pt – active charcoal are often rapidly deactivated, soluble complexes such as hexachloroplatinic acid (Speier catalyst) [58] are now used. These are added in high-boiling solvents such as dichlorobenzene and lead to formation of the desired vinylsilanes in >90 % yield without overpressure [115]. Through control of the temperature and reagent stoichiometry, the target product can also be removed continuously from the reactor [116]. In this way the subsequent reaction to give the diadduct, which acts simultaneously as a solvent, is suppressed still further. Addition reactions of alkylsilanes ($RHSiCl_2$) or H-substituted siloxanes proceed analogously. In particular, reactions with dichloromethyl- and chlorodimethylsilane are of industrial interest; those with the less reactive H_2SiCl_2 are somewhat less so.

Vinyl compounds can also be obtained from vinyl chloride by substitution reactions of Si–H bonds (see Section 2.5) [67].

The Grignard synthesis is worthwhile only for vinyl-rich intermediates that are virtually inaccessible by hydrosilylation.

Allyl compounds are also produced on a large scale. Tri- and dichloroallylsilanes can be prepared by replacing the halogen (e.g., in allyl chloride) with H-silanes. The resulting condensation with loss of HCl can be carried out at elevated temperature or with tertiary amines and CuCl as an effective catalyst [117, 118]. The allyl group can also be generated by subsequent HCl elimination from chloropropylsilanes, which are available on an industrial scale. Like the allyldimethylsilyl chain stoppers, these compounds also play an important role as reactive building blocks for polysiloxanes. The monochlorosilane precursor is produced better by cleavage of methyl-rich disilanes with allyl chloride, as is allyltrimethylsilane, used in pharmaceutical synthesis [64, 119]. The Grignard coupling of $CH_2{=}CHCH_2X$ with Si–X compounds (Section 2.2) is the most universal method, but because of the low time–space yield, it is limited to laboratory syntheses and the production of intermediates that cannot be produced directly by the above methods.

The lower stability of the Si–C bond toward strong acids and bases, compared with vinylsilanes, is also a sign of the special reactivity of the allyl group.

Other industrially interesting alkenyl compounds include adducts of H-sil(ox)anes with vinylcyclohexene, linear diolefins, or substituted alkynes.

The addition of trichlorosilane or dichloromethylsilane to vinylcyclohexene gives the desired cyclohexenylethyl compound with excellent selectivity because of the considerably higher reactivity of the terminal double bond. The cyclohexene structure is, moreover, suitable for the production of epoxysilanes and epoxysiloxanes (see Section 4.5.1) after replacement of the chlorine substituent. The process is more difficult to control when several double bonds of equal reactivity are present in the starting material. Diolefins such as hexadiene or octadiene must be present in at least two- to fourfold excess if good yields of the monoadduct are desired. Isomers derived from internal olefin structures may also be formed.

The resulting alkenylsilicon compounds are used, like the allyl derivatives, for particularly reactive silicones [e.g., LTC (low-temperature curing) systems for coating plastic films or paper] [120]. Such systems can also be produced by incorporating industrially relevant allyl ether precursors. Some of these newly developed siloxanes can even be cross-linked cationically after rearrangement of the allyl group to a propenyloxy group (cf. vinyl ethers) [121].

Butadiene gives mono adducts with high selectivity, but the resulting allylsilanes ($\equiv SiCH_2CH{=}CHCH_3$) are not suitable for addition reactions because of the terminal methyl group.

Sil(ox)anes with a butadienyl substituent are, like the conjugated diolefin itself, very reactive. Such compounds can easily be produced by the hydrosilylation of butynols, which are available on an industrial scale [122]. Monoaddition to the triple bond (Eq. 55) is highly selective and gives two isomeric adducts, both of which readily eliminate water.

This elimination is generally carried out in situ, in the presence of the next reaction partner, which then becomes bonded to the isoprenylsilicon intermediate, for example, in a [2 + 4] cycloaddition (see Section 4.5.3).

Silylacetylenes can be produced relatively easily (e.g., from chlorosilanes and acetylene derivatives), but because of their low stability, particularly toward protic compounds, they have not achieved industrial importance thus far.

4.2. Organohalogenated Compounds

Silanes with halogen-containing side groups play a key role in silicone chemistry and particularly as reactive intermediates for the introduction of various Y functions. The downstream products of allyl chloride are the most important. 3- or γ-chloropropylsilanes are produced on a large scale. The production process starts with a catalytic addition, which is

often carried out continuously (see Scheme 2). In the case of trichlorosilane it gives the desired chloropropylsilane with a selectivity up to ca. 83 % [123]. The formation and addition of propene, occurring as a side reaction, can be interpreted as Cl−H exchange. It increases in the order $HSiCl_3 < MeHSiCl_2 < Me_2HSiCl < Me_2HSiPh$ [124]. The resulting losses can, however, also be explained by the intermediate decomposition of a β-adduct, which is perhaps therefore not isolable. Accordingly, methallyl chloride gives fewer side products.

Scheme 2. Addition of silanes to allyl chloride

The (chloropropyl)chlorosilanes are alkoxylated on a large scale by a reaction analogous to that shown in Equation (33) (Section 3.2). The methoxy and ethoxy derivatives are almost the only industrially important ones. They are additives for various formulations and, in particular, reactive intermediates for the production of other organofunctional silanes. They are also accessible directly by a new process starting from allyl chloride and H-alkoxysilanes with iridium catalysts [125].

The corresponding bromo- and iodopropyl compounds are of only minor importance, despite their higher reactivity in nucleophilic reactions, since the addition of iodine or phase-transfer catalysts is generally sufficient to activate the organochlorine group.

Chloromethyl compounds have achieved a certain importance (e.g., in the synthesis of biologically active substances) because of the many derivatives that can be formed from them (see Section 6.2). They are generally produced by radical chlorination of methylsilanes from the direct synthesis. Such processes generally exhibit modest selectivities and in the silicone industry are used only for methyltrichloroand chlorotrimethylsilane. The corresponding monochlorinated derivatives, $ClCH_2SiCl_3$ and $ClCH_2(CH_3)_2SiCl$, can be used in the same way as the chloropropylsilanes described above. Compounds with additional organic functional groups can be obtained from chloromethyllithium as the reactive intermediate [126].

Chlorophenylsilanes are produced by direct chlorination with Friedel – Crafts catalysts. Substitution in the aromatic ring leads to stabilization, making the compounds suitable for high-temperature applications.

β-Chloroethylsilanes show exceptionally high reactivity, which is further enhanced in the presence of bases. These compounds are readily produced by the reaction of gaseous HCl with chlorovinylsilanes, which undergo smooth anti-Markovnikov addition in the presence of soluble aluminum catalysts [127]. The terminal carbon atom is rendered positively charged by the so-called β-effect, and the loss of the anionic leaving group is activated. In the presence of moisture the functional group decomposes according to Equation (56). The rate of ethylene formation depends on the pH and the nature of the groups bonded to silicon [128]. This has been used to control ripening processes.

Industrial fluoroorganosilanes differ fundamentally from the organohalogen compounds considered thus far. The systems that are of interest in industrial applications are strictly speaking not organofunctional since they are actually very inert. Because α- and β-C-fluorinated compounds are of comparatively low stability, fluoro substituents are incorporated only from the γ-position onward. The most important monomers are derived from 3,3,3-trifluoropropene. Trifluoropropylsilanes are produced by the catalytic addition of H-silanes.

Longer- chain highly fluorinated side groups lead to considerably lower surface tension. A monolayer of $CF_3(CF_2)_7CH_2CH_3SiO\equiv$ reaches values of < 8 mN/m [129]. In practical applications, such substituents, which can also be introduced by hydrosilylation, give partic-

ularly favorable effects with regard to solvent resistance, wettability, and adhesion/release. In addition, syntheses with SiH – fluoroaromatics (condensation, H_2 cleavage), Cl–F exchange, or Grignard precursors are known but have not achieved industrial importance.

4.3. Nitrogen-Containing Compounds

Parallel to the development of vinyl systems, nitrogen derivatives – in particular aminoorganosilanes – gained increasing industrial importance. These very reactive compounds play an important role in many silicone formulations, as well as in a large number of other applications involving compatibility, adhesion, or bonding of different substrates.

4.3.1. Cyanoalkyl Compounds

Cyanoethylsilanes were synthesized very early on by Si–H additions of chlorosilanes to acrylonitrile. Such processes have been carried out on a large scale since reduction of the alkoxylated downstream products to give the industrially interesting aminopropyl group became possible [130]. The acrylonitrile process is, however, carried out not with the usual transition-metal catalysts (which sometimes give the unstable α-adducts exclusively), but in the presence of tertiary amines or phosphines. Presumably, anionic intermediates are involved [131].

$$Cl_3SiH \xrightarrow{NR_3} \{Cl_3S\bar{i} - H - \overset{+}{N}R_3\} \xrightarrow{CH_2=CHCN} Cl_3SiCH_2CH_2CN \qquad (57)$$

Addition of CuCl leads to more effective systems [132]. The corresponding trialkoxy compounds are produced by an alkoxylation process analogous to that described in Section 3.2 or by the addition of HCN to alkoxyvinylsilanes [133].

Longer- chain cyano compounds can be produced by noble-metal-catalyzed hydrosilylation of alkenyl nitriles such as allyl cyanide. The resulting cyanopropylsilanes are used, for example, in chromatography.

Organically bonded nitrile functions can be hydrolyzed to give free carboxylic acids. Hydrogenation is described in Section 4.3.2.

4.3.2. Organic Amino Compounds

Aminopropyl systems are the most important organofunctional sil(ox)anes. "Primary" aminosilanes are preferred because of their high reactivity.

Aminopropyltriethoxysilane [*919-30-2*], the most important individual compound, can be produced by three methods.

The acrylonitrile process (Section 4.3.1) is still regarded as very economical despite the necessary expenditures for safety. Cyanoethylsilane originating from the addition step (Eq. 57) is ethoxylated and then hydrogenated over Raney nickel at high hydrogen pressure [130].

$$Cl_3SiCH_2CH_2-CN \xrightarrow[2)\ H_2,\ Ni]{1)\ EtOH} (EtO)_3SiCH_2CH_2CH_2-NH_2 \qquad (58)$$

The hydrosilylation of allylamine appears as a direct route to be actually simpler than the other, multistage processes, which in addition require pressurized reactors. The addition of triethoxysilane is, however, somewhat inhibited with the normal platinum catalysts and gives too much of the β-adduct (i.e., internal addition, 10 – 25 %), which causes problems in many applications. Rhodium phosphine complexes increase the overall yield of the desired γ-product to > 80 % so that the process now appears to be competitive [134].

$$(EtO)_3SiH + CH_2=CHCH_2NH_2 \xrightarrow{Rh} (EtO)_3SiCH_2CH_2CH_2NH_2 + (EtO)_3Si\overset{Me}{\overset{|}{C}}HCH_2NH_2,\ Si(OEt)_4,\ H_2 \qquad (59)$$

This reaction is an example of the advantageous use of expensive rhodium compounds, which generally exhibit higher selectivity and lower sensitivity to inhibiting substances. The reaction mode and yield are now comparable to those of the more reactive (and with platinum compounds sufficiently selective) *N*-trimethylsilylallylamine [65].

The ammonia substitution process starts from chloropropyltriethoxysilane [*5089-70-3*], and requires a large excess and high pressure of NH_3.

With a 75-fold molar quantity of NH_3 with respect to the chloro component, selectivities for the primary amine of up to 81 % have been reported [135]. The correspondingly low space–time yields can only be improved if increased proportions of di- and even trisubstituted downstream products of the initially formed aminopropylsilane are acceptable.

$$(RO)_3SiCH_2CH_2CH_2Cl \xrightarrow{NH_3} [(RO)_3SiCH_2CH_2CH_2]_nNH_{(3-n)} \quad (60)$$

Whether the NH_3 process is economical depends strongly on the possibilities for using the side products, particularly the bis(3-trialkoxysilylpropyl)amine (e.g., as coupling agents).

The substitution process with primary or even secondary amines or with ethylene-bridged polyamines as the nucleophiles is considered more advantageous. γ-(Ethylenediamino)propylalkoxysilanes are produced industrially by a reaction analogous to Equation (60). A three- to fivefold excess of diamine is generally sufficient to achieve yields of monomer $> 80\,\%$. One equivalent of the strong base acts as an HCl acceptor and forms a readily separable liquid phase. The very reactive methoxy compounds are of particular industrial importance.

In many applications *N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane [*1760-24-3*] competes with or supplements aminopropyltriethoxysilane, the most widespread organofunctional silane. The analogous dimethoxymethylaminosilane [*3069-29-2*] is the active building block of many amine fluids (for treating textiles, etc.).

Other important amino compounds are the *N*-methyl-, *N,N*-dimethyl-, and *N*- cyclohexylaminopropylsilanes. These are also produced by the substitution process. Here the removal of the amine hydrochloride, which is produced simultaneously, is problematic. Chloride-free pure products in good yields are obtained only after subsequent treatment with alkoxides or other strong bases [124]. Such secondary or tertiary amino groups impart advantages in certain applications (e.g., less thermal yellowing). They can therefore be considered alternatives to the standard silanes discussed previously. They are also used in the preparation of quaternary ammonium and betaine structures.

Organic amino functions at the end of siloxane chains are becoming increasingly important for the synthesis of block structures with organic polymer segments. Primary amino groups are preferred.

Bis(aminopropyl)tetramethyldisiloxane (aminopropyl chain stopper [*2469-55-8*]) is not sufficiently accessible either by substitution with NH_3 or by a route analogous to Equation (57). Since the direct addition of tetramethyldisiloxane (cf. Eq. 59) is also unsatisfactory, cyclic hydrosilylation of the silazane from chlorodimethylsilane and allylamine has been proposed [136].

$$CH_2{=}CH_2CH_2{-}NH{-}Si(Me)_2H \xrightarrow{Pt} Me_2\overline{SiCH_2CH_2CH_2{-}NH} \quad (61)$$

The resulting Si–N ring is very reactive and can be cleaved hydrolytically to give the free aminopropyl group. The route involving phthalimide (Gabriel synthesis) or the treatment of the corresponding chloropropyldisiloxane with sodium diformylamide appears to be more straightforward [137].

As an alternative for certain applications the ethylenediaminopropyl stopper function may be considered, which is readily produced by direct substitution (cf. Eq. 60).

Aromatic amino compounds, which are used for the modification of particularly thermostable composites (e.g., in polyimides) can be produced by hydrogenation of nitrophenyl precursors (accessible according to Eq. 66 [138]).

4.3.3. Other Nitrogen Compounds

Other interesting nitrogen compounds can be produced by nucleophilic substitution of chloropropylsilanes, including isocyanate, urethane, ureido [123], and imidazole derivatives. Some of these compounds can also be produced by hydrosilylation of the corresponding allyl precursors and further derivatization. They are versatile intermediates in silicone chemistry.

Quaternary ammonium compounds (quats) are produced mainly by substitution reactions

of chloropropyl precursors. The reaction with long-chain amines such as octadecyldimethylamine [139] is of industrial importance because it leads to surface-fixable biocides (Section 6.2). Methyl-substituted quats, which are also accessible from alkylaminosilanes, such as the side products shown in Equation (60) ($n = 2, 3$) act as ion exchangers and, if the chains are longer, also as phase-transfer catalysts [123].

The many compounds produced from aminosilanes include the cationic styrene compound $CH_2{=}CHC_6H_4CH_2N^+H_2CH_2CH_2NH{-}CH_2CH_2CH_2Si(OMe)_3$ [*34937-00-3*], which is produced by substitution of *p*-vinylbenzyl chloride and was introduced in 1972 as a copolymerizable coupling agent [114].

4.4. Organosulfur Compounds

4.4.1. Mercapto and Sulfidic Organofunctions

Mercaptofunctional silanes with spacers of more than one carbon between sulfur and silicon were reported as stable compounds in the early 1960s. These monomers, which are important in the rubber industry, are produced mainly from the corresponding chloropropyl precursors. Since alkali-metal hydrogensulfides give too much bis(silylpropyl)sulfide in this reaction, the mercaptopropyl compound can, in practice, be obtained directly only with H_2S – amine combinations [140]. Pure monomers are better produced from protected *S*-nucleophiles such as thiourea. The isothiuronium salts formed initially are then cleaved with base (e.g., ammonia).

$$(RO)_{3-n}Me_nSi(CH_2)_3Cl \xrightarrow{+\,S{=}C(NH_2)_2} (RO)_{3-n}Me_n\,Si(CH_2)_3S^+C(NH_2)_2Cl^- \xrightarrow[-(H_2N)_2C{=}NH_2{}^+Cl^-]{+\,NH_3} (RO)_{3-n}Me_nSi(CH_2)_3{-}SH \quad (62)$$

Since complete separation of the guanidinium salts is often difficult, addition of solvents or cleavage with alkylamines, which form liquid phases, has been proposed [123, 141]. The same mercapto compounds can also be produced by addition of H_2S to the corresponding cyanoethylsilanes or by their reductive cleavage with $H_2{-}CoS_x$ [142]. β-Mercaptoethyl compounds can be produced from vinyl compounds and H_2S [143].

The thiol group is very versatile, bonding, for example, by radical addition to alkenyl systems under mild conditions. This predominantly anti-Markovnikov addition is of considerable industrial importance in the cross-linking of various polymers.

Silanes with sulfidic sulfur bridges are of considerable industrial importance. They are produced mostly by direct substitution with sodium polysulfides Na_2S_x [123]. The average chain length of S_x is decisive for the reactivity of the compounds (e.g., in rubber vulcanization). The chain length can be regulated by addition of sulfur or by adjusting the pH during substitution with disodium tetrasulfide. This process is used industrially on a large scale. The most important compound, the tetrasulfane $[(EtO)_3SiCH_2CH_2CH_2]_2S_4$ [*40372-72-3*], is used as a strengthening additive for the treatment of fillers and for the cross-linking (vulcanization) of polyolefin elastomers.

Disulfidic compounds, whose sulfur bridges can be readily cleaved by oxidation (see Section 4.4.2) or reversible reduction to thiol groups, can be obtained by the same route.

4.4.2. Compounds Containing Sulfur – Oxygen Groups

The ready oxidizability of sulfidic sulfur compounds (e.g., with H_2O_2) is used for the synthesis of sulfonate-functional siloxanes, which are used as ion exchangers, for example [144].

Such groups are preferably produced directly from the corresponding chloropropyl precursors. Substitution with Na_2SO_3 gives sulfopropylsilane – silanol intermediates, which are suitable for the production of hydrophilic to tensidic silicone oils [145]. Sulfoethylsilanols can be synthesized from vinylsilanes and bisulfite [146].

Thiosulfate groups are introduced by direct substitution with $S_2O_3^{2-}$ (Eq. 63) [147]. The organically bonded thiosulfate group (Bunte salt) undergoes hydrolytic cleavage to give mercaptopropylsiloxanes.

$$(RO)_{3-n}Me_nSi(CH_2)_3Cl \xrightarrow[-NaCl]{+\,Na_2S_2O_3,\ H_2O} (RO)_{3-n}Me_nSi(CH_2)_3S_2O_3^-\ Na^+ \quad (63)$$

Compounds in which sulfur is bonded via oxygen are generally less stable to hydrolysis and are not dealt with here.

4.5. Oxygen-Containing Compounds

4.5.1. Epoxy and Other Oxy Compounds

In epoxy groups, oxygen is part of a highly activated ring structure. Since oxiranes can be opened even by traces of HCl, chlorosilanes are generally not suitable as starting materials. Industrial production of such silicon compounds starts mostly from alkoxy H-silanes or siloxanes and epoxidized alkenes such as allyl glycidyl ether or vinylcyclohexene oxide [124, 148]. Hydrosilylation with chlorine-free platinum catalysts or, for less pure reactants, with rhodium catalysts leads directly to monomers such as 3-glycidoxypropyltrimethoxysilane [*2530-83-8*] or 3,4-epoxycyclohexylethyltrimethoxysilane [*3388-04-3*], which are used as, e.g., coupling agents (Section 6.7).

The epoxidation of alkenylsil(ox)anes (Eq. 64) avoids toxic, potentially mutagenic, oxirane precursors [149, 150].

(64)

This relatively mild oxidation is particularly suitable for polysiloxanes with epoxy groups in the chain. The degree of functionality can be controlled most readily by equilibration with the alkenylsilane precursor.

Whereas vinylic oxiranes, such as the α- or β- chloro or hydroxy compounds, rearrange relatively easily or eliminate olefins (Peterson reaction [151]), higher epoxy compounds behave like their organic analogues. Their high reactivity with acids and, in particular, with nucleophiles has led to a large number of individual applications.

Hydroxyalkyl groups are stable only if the OH group is in the γ-position or further from the silicon; they then react like normal alcohols. Direct hydrosilylation of allyl alcohol is now rarely used industrially because of considerable hydrogen formation in alcoholysis side reactions [124] and because of the toxicity of the alcohol. Since these problems are only partially solved by using silyl protecting groups, less critical precursors are used, such as allyl acetals or allyl esters, which can be hydrolyzed readily to hydroxy compounds after Si–H addition. Comparable intermediates are also obtained by the esterification of chloropropyl precursors with carboxylic acid salts. Similar hydroxy compounds are accessible by hydrosilylation of higher alkenols or glycol monoallyl ethers. Losses due to alcoholysis decrease with increasing chain length and with decreasing polarity of the components. This also holds for the addition to allylphenol.

Longer-chain poly(ethylene glycol) or poly (propylene glycol), which lead to systems with hydrophilic to tensidic properties, are added in the form of their monoallyl ethers, mostly directly to the oligomeric sil(ox)anes (siloxanes–oxyalkylenes, etc.).

Hydroxyl groups can also be formed by reaction of *O*-nucleophiles, in the simplest case water, with epoxyalkylsilanes.

4.5.2. Acrylates and Other Ester Functions

As early as 1963, methacrylic-functional silanes were introduced as particularly effective modifiers for organic polymers containing carboxyl groups. These are produced almost exclusively by hydrosilylation of allyl methacrylate (Eq. 65) [24].

$$X_3Si{-}H + H_2C{=}CHCH_2OCO\overset{Me}{\overset{|}{C}}{=}CH_2 \xrightarrow{Pt} X_3Si(CH_2)_3OCO\overset{Me}{\overset{|}{C}}{=}CH_2 \quad (65)$$

This reaction leads to the desired 3-methacryloxypropyl group with good selectivity because of the considerably higher reactivity of the allyl group. The most important of these compounds, the trimethoxy compound [*2530-85-0*] (X = OMe), is produced industrially either by direct addition of trimethoxysilane or preferably via the corresponding trichlorosilyl

precursor [*7351-61-3*] (X = Cl) in the presence of radical scavengers [152]. The second method provides access to other alkoxy derivatives.

The reaction of γ-functional precursors with acrylates is an alternative. Chloropropylsil(ox)anes can, for example, be esterified directly with salts of acrylic or methacrylic acid. Such processes, which are carried out in solution or heterogeneously with phase-transfer catalysts, are particularly suitable for products richer in siliconbound methyl groups, which are less readily accessible from allyl acrylates. The formation of esters from hydroxypropyl precursors and acrylic acid or the comparable transesterification with methyl methacrylate in the presence of tin catalysts [153] is preferably carried out on linear siloxanes. According to patents, similar systems can be produced by reaction of aminofunctional sil(ox)anes with acrylic acid chloride [154].

Other oxygen-bonded esters include the acyloxypropylsil(ox)anes discussed in Section 4.5.1.

Alkyl-bonded esters, such as the addition products of acrylates and vinylacetic acid, are dealt with in Section 4.5.3.

4.5.3. Acid Anhydrides and Other Carboxy Groups

Carboxy compounds play an important role in industrial polymer chemistry because of their dipolar nature. The modification of such systems can take place by radical grafting with acrylate groups or by nucleophilic coupling with activated carboxyl groups.

Anhydride-functional silicon compounds are particularly suitable for this. The introduction of such side groups is generally carried out by hydrosilylation of appropriate alkenyl precursors. Whereas the addition of sil(ox)anes to 5-norbornene-2,3-dicarboxylic acid anhydride [*826-62-0*] leads only to mixtures of isomers that are difficult to purify [155], the analogous reaction with allylsuccinic acid anhydride [*7539-12-0*] gives readily distillable monomers. The easy-to-handle 3-triethoxysilylpropylsuccinic acid anhydride [*93042-68-3*] is of particular interest [156].

Carboxyorgano groups can also be introduced into silanes by palladium-catalyzed reaction of disilanes with aromatic acid chlorides (e.g., from 1,2,4-benzenetricarboxylic anhydride [*1204-28-0*]) [138].

4-(Chlorodimethylsilyl)phthalic anhydride [*116088-82-5*], produced by this route, can be used as a stopper function for bonding longer-chain siloxanes to OH- or NH-functional organic blocks. Comparable structures are synthesized better by the [2 + 4] cycloaddition of maleic anhydride to the isoprenyl (butadienyl) compounds described in Section 4.1 [157].

The hydrosilylation of acrylates has attracted renewed interest as a result of the use of silylketene acetals in group-transfer polymerization (GTP, see Section 6.5). The resulting reactive intermediates can be regarded as neutral silyl-transfer agents like the α-silyl esters, which contain a labile Si−C bond. Such compounds, which are relatively unstable compared to silicones, are formed along with others in the hydrosilylation of acrylic esters [158].

The product ratio depends on the ester group, the catalyst used, and especially on the starting silane and the stoichiometry. The stable β-adducts are mainly of interest in silicone chemistry.

Methacrylic esters give terminal products with considerably higher selectivity, particularly

when dichloromethylsilane is the H- component [24]. The resulting propionates can be equilibrated into organosiloxanes and subsequently saponified to the free acid, as is possible for cyanoalkyl groups under more forcing conditions.

Such carboxy-functional siloxanes have been produced from the corresponding silalactones [159]. The ester bond of the β-adducts is activated by the neighboring Si−Cl group, so that even catalytic quantities of tertiary or quaternary bases B are sufficient to liberate R^1Cl (usually chloromethane) according to Equation (69).

(69)

Above 130 °C the lactones gradually rearrange into oligomeric acid chlorides [160], which are also suitable for the production of propionate-functional organosiloxanes.

Longer- chain carboxy functions are accessible by hydrosilylation of the trimethylsilyl esters of vinylacetic acid, undeceneoic acid, etc. [161].

The organometallic introduction of acid groups via haloalkyl precursors and carbonyl compounds with activated CH groups, or by using magnesium and CO_2, appears too costly for industrial applications.

Direct nucleophilic substitution of haloalkylsilanes with carboxylates plays a significant role. Besides the monoesters or amides of dicarboxylic acids, derivatives of chloroacetic acid should be mentioned in particular here.

Treatment of chloroacetic acid derivatives with dialkylaminopropylsil(ox)anes gives betaine-modified products, which are intended for cosmetic and tenside applications [162]. Similar carboxy-functional products are also accessible via mercaptoacetic acid [163].

4.6. Other Organofunctions

Carbon-bonded phosphorus groups are particularly stable in the β-position or further from silicon. The phosphonate esters $\equiv SiCH_2CH_2-P(O)(OR)_2$ can, for example, be saponified with strong acids without cleaving the ethylene bridge between the heteroatoms [164]. These compounds, which are of major industrial interest (see Section 6.4), are produced by radical addition of phosphite esters to vinylalkoxysilanes (hydrophosphorylation). The reaction with diethyl phosphite in the presence of peroxide catalyst to give 2-(diethylphosphono)ethyltriethoxysilane [*757-44-8*] is carried out on a large scale [165]. Similar phosphonate esters can be obtained by the Arbuzov reaction of trialkyl phosphites with haloalkylsilanes.

Phosphine groups can also be introduced by radical addition (e.g., of $HPPh_2$ to vinylsilanes) or by substitution with alkali-metal phosphides [166]. Such ligands are suitable for fixing noble metals, particularly rhodium catalysts.

Organometallic groups bound to organosilyl groups directly or via carbon bridges generally occur only as reactive intermediates in the synthesis of the compounds discussed here. Examples are ferrocene, titanium, or tin complexes, numerous Grignard reagents, and the π/σ-bonded active catalysts of various hydrosilylation reactions. They are not described in detail here.

5. Other Organosilanes

5.1. Tetraorganosilanes

In tetraorganosilanes, four organic groups are bonded to silicon via carbon. Symmetrical compounds have four identical organic substituents, and unsymmetrical ones up to four different organic groups on silicon. Carbosilanes, compounds in which silyl groups are bonded, for example, via CH_2 groups also belong to this class [30].

Production. Symmetrical tetraorganosilanes are generally produced by treatment of SiX_4 (X = halogen, OR, H) with organometallic reagents [167]. Tetramethylsilane is formed in small quantities in the direct synthesis. It is also produced as the target product by treatment of Me_3SiCl with methyl Grignard. For the synthesis of unsymmetrical products, numerous processes have been proposed in which $SiCl_4$ or R_nSiX_{4-n} ($n = 1-3$, X = mostly halogen) is treated with mixtures of organometallic reagents; for examples, see [168].

Properties and Uses. Tetraorganosilanes are relatively inert chemically except for compounds bearing organofunctional groups. Pyrolytic decomposition of tetramethylsilane occurs only above 600 °C. This compound is attacked only slowly by concentrated sulfuric acid (Eq. 70).

$$Me_4Si \xrightarrow{H_2SO_4} Me_3SiOSiMe_3 + CH_4 \quad (70)$$

Tetraorganosilanes can, however, be used as alkylating agents [169] (Eq. 7).

$$R-\overset{\overset{O}{\|}}{C}-Cl + Me_3Si-C\equiv C-R^1 \xrightarrow{AlCl_3} R-\overset{\overset{O}{\|}}{C}-C\equiv C-R^1 + Me_3SiCl \quad (71)$$

Tetramethylsilane is used in coproportionation reactions [170] (see Section 2.6). It is also used as a reference in ^1H, ^{13}C, and ^{29}Si NMR spectroscopy and to fill ionization chambers in particle accelerators [171].

5.2. Disilanes

Chloromethyldisilanes $Me_nSi_2Cl_{6-n}$ ($n = 1-6$) are formed as side products in the direct synthesis (3 – 8 % in the crude silane). Only hexamethyldisilane [*1450-14-2*] is produced specifically and on a large scale from Me_3SiCl by the Wurtz reaction (Eq. 72).

$$2\,Me_3SiCl + 2\,Na \longrightarrow Me_6Si_2 + 2\,NaCl \quad (72)$$

To achieve complete conversion of sodium, many process variants have been proposed; see, for example, [172]. The electrochemical synthesis of Me_6Si_2 from Me_3SiCl is still not used in industry [173]. Most of the disilane fraction from the direct synthesis ($Me_nSi_2Cl_{6-n}$, $n = 1-6$, main products $n = 2-4$) is cleaved to give monosilanes. On acidic cleavage with hydrogen chloride, H- containing silanes are also obtained (Eq. 73).

$$Me_2ClSi-SiMeCl_2 + HCl \xrightarrow{Cat.} Me_2SiCl_2 + MeHSiCl_2 \quad (73)$$

Cleavage with amine- or phosphorus- containing catalysts gives chlorine- containing polysilanes as well as monosilanes [174]. Chlorine-free polysilanes can be produced as the target product by disproportionation of methoxymethyldisilanes in the presence of NaOMe [175].

The synthetic potential of disilanes is noticeably gaining interest in industry. Besides the reactions described above, a range of methods has been developed in which new Si–C bonds can be formed by catalytic cleavage of the Si–Si bond. An example is shown in Equation (66). For further examples, see [176].

5.3. Polysilanes

Organopolysilanes are compounds in which organosilyl groups are linked by Si–Si bonds. They are increasingly being used as starting materials for silicon carbide ceramics, fibers [177] (see also → Fibers, 5. Synthetic Organic, Chap. 3.2.2.), and composites derived therefrom [178]; as photoresists in microelectronics; and as photoinitiators. They also possess nonlinear optical properties. The production, properties, and uses of polysilanes are described in → Inorganic Polymers, Chap. 2. A more recent review can be found in [179].

6. Uses

The rapid development of industrial silane syntheses created economical access to completely new substances, reaction principles, and surprising applications. The possible uses of mono- and oligomeric organosil(ox)anes, apart from the production of polymeric silicones (see → Silicones), are given below (see also Chap. 4). Only some important uses are described here. Further information can be found in [123, 180].

6.1. Silylating Agents

Silanes have long been used in pharmaceutical research and production. One group of processes is characterized by the fact that silicon compounds enter only temporarily into the production cycle of the target product.

Silanes as Protecting Groups. In organic synthesis the presence of sensitive protic groups (OH, NH, COOH) can hinder reactions or make purification more difficult. These problems can be circumvented by temporarily substituting the protons using suitable silylating agents R_3SiX (X = halogen, amine, amide; see Table 5) [181]. The choice of the X group must take into consideration the possible pH sensitivity of the substrate molecule. The protecting group R_3Si can generally be introduced with high reactivity and selectivity. It can activate desired reactions or hinder undesired attack in another position. The derivatized molecule exhibits better solubility in organic solvents and increased volatility due to the absence of hydrogen bonds. After the desired reactions have been carried out, the protecting group is carefully removed by alcoholysis or hydrolysis, to finally form $Me_3SiOSiMe_3$ (HMDSO). To increase the overall economy and decrease environmental pollution, recycling of Me_3Si groups has been established since 1972 (Fig. 3). About 70 % of the HMDSO wastes returned to the silicone producers can be recovered. The cleavage of HMDSO to give chlorotrimethylsilane can, for example, take place by continuous reaction with dichlorodimethylsilane [89] or hydrogen chloride [182]. The more selective, nitrogen-containing, silylating agents that can be produced from it (Section 3.5) are quite inert in the pure state toward the groups to be protected (and also to moisture). By addition of acids or metal catalysts their activity is drastically increased under certain conditions.

Figure 3. Recycling of Me_3Si protecting groups

One of the most important uses of trimethylsilanes is in the production of completely or semisynthetic β-lactam antibiotics; for this and the use of more recent silylating agents, see [75, 181, 183].

The use of silanes as reagents in organic synthesis has also been investigated intensively [8, 184]. The stereochemical behavior of organosilanes is particularly interesting [187]. Relatively little is known of the extent to which this has been exploited industrially.

Silanes for Enzyme Immobilization. Many biotechnological processes [186] involve the covalent anchoring of enzymatically active macromolecules on inert carriers (e.g., porous glass) over which the reaction medium is (continuously) passed. One variant of this is covalent bonding by using silane coupling agents [123] (see Section 6.7).

6.2. Physiologically Active Organosilicon Compounds

In physiologically active organosilicon compounds at least one silicon atom is a component of the active molecule itself. Because of the differences in reactivity between carbon and silicon atoms, in some cases the synthesis can be carried out more specifically and in higher yield than with the carbon analogue [187].

In many cases the silicon compound has modified activity. Provided hydrolysis of the SiOC bonds can occur, they are degraded more rapidly in the organism and thus permit a higher dosage with fewer side effects under certain circumstances.

Organosilicon Pharmaceuticals. The above-mentioned organosilanes exhibit specific physiological activity only in exceptional cases (Chapter 7). Following the relatively late discovery and investigation of silatranes **5** (from ca. 1960 onward) [25], which have a unique, broad spectrum of activity depending on the structure of the SiC-bonded group, a range of potential organosilicon pharmaceuticals has been systematically researched [188].

Table 5. Important silanes for introduction of protecting groups

Chemical name	Structure	CAS no.	Cleavage product
For standard applications			
Dichlorodimethylsilane	Me_2SiCl_2	[*75-78-5*]	acidic
Chlorotrimethylsilane ∗	Me_3SiCl	[*75-77-4*]	acidic
Hexamethyldisilazane ∗	$(Me_3Si)_2NH$	[*999-97-3*]	alkaline
N,N′-Bis(trimethylsilyl)urea ∗	$(Me_3SiNH)_2CO$	[*18297-63-7*]	neutral
For special applications			
N,O-Bis(trimethylsilyl)acetamide ∗	$CH_3C[{=}NSi(CH_3)_3]OSi(CH_3)_3$	[*10416-59-8*]	neutral
Iodotrimethylsilane ∗	Me_3SiI	[*16029-98-4*]	acidic
Hexamethyldisilane ∗	$Me_3SiSiMe_3$	[*1450-14-2*]	
tert-Butylchlorodimethylsilane	Me_3CSiMe_2Cl	[*18162-48-6*]	acidic

∗ Incorporated into industrial Me_3Si recycling.
∗∗ The highly reactive 1 : 1 molar mixture gives NH_4Cl.

5

Only a few of these agents are used in the treatment of humans: Cisobitan (against prostate cancer) in Northern Europe; Migugen and Mival (hair growth and wound-healing agents) in the CIS.

Organosilicon Biocides. Tetraorganosilanes with specific substitution in (hetero)aromatic ring systems have achieved importance as biocides. The first important market product was the broad-spectrum fungicide Flusilazol (**6**) [189], which is soon to be followed by the insecticide Silafluofen (**7**) [190].

6 [*85509-19-9*]

7 [*105024-66-6*]

The antimicrobial activity typical of ammonium compounds with longer-chain alkyl substituents is also exhibited by silanes such as $(RO)_3Si(CH_2)_3N^+MeR_1R_2Cl^-$. Here the Si function acts only as an anchor toward mineral substrates or organic fibers. The primary uses are in the treatment of textiles (carpets, sportswear) and the purification of water [191].

6.3. Silanes for Silicone Modification

A relatively small range of moisture-sensitive organosilanes is used as cross-linking agents in cold-cross-linking silicone sealants (RTV systems; see → Silicones, Chap. 4.4.3.). The most important compounds are listed in Table 6. The quantities used are several thousand tonnes per year. Silane coupling agents can also be used for cross-linking (see Section 6.7) [192].

Organofunctional silicones are obtained by introducing the corresponding silanes (see Table 7) into polysiloxanes by condensation or equilibration reactions. The generally fluid products are used in reprography, in textile finishing, and in polish additives.

In coating technology, specific oligosiloxanes that undergo cross-linking by cationic ring-opening polymerization are now used [193]. In the production of siliconized release paper, the reaction of dimethylpolysiloxanes or methylcyclosiloxanes containing 2-(3-epoxycyclohexyl)-ethyl groups is initiated by strong Brönsted acids. The latter are formed, for example, from diaryliodonium salts on UV irradiation [194]. The reaction is not inhibited by oxygen.

6.4. Silanes for Modification of Organic Polymers

Organosil(ox)anes are being used increasingly for improving the production and properties of polymers.

Cross-Linking of Polyethylene. In some applications the SiOH condensation mechanism,

which is so successful for silicones, is used for cross-linking and better adhesion. Two industrial processes were introduced in the 1970s under the names Sioplas and Monosil, in which trimethoxyvinylsilane [*2768-02-7*] is grafted onto polyethylene (PE, sometimes modified) by means of dicumyl peroxide (DICUP) [195]. Although the industrial processes differ (Fig. 4), the reaction principle is identical. After molding, the silyl function bonded to the polymer via an ethylene bridge is hydrolyzed by external moisture (hot water bath, steam). The resulting silanol groups then undergo cross-linking, which is catalyzed by premixed dibutyltin dilaurate (DBTL) [*77-58-7*] (Eq. 74).

The Sioplas process separately produces two granulated polyethylene compounds in classical hot mixers. These are stored temporarily and can later be extruded as ca. 19 : 1 mixture with standard equipment. In a new process variant [196], vinylsilane is copolymerized with ethylene under high pressure. The resulting peroxide-free compound 1 (in Fig. 4) is very uniform and more stable to storage than grafted types. The cross-linked products are used in quantities of several hundred thousand tonnes per year as insulating materials, predominantly in low-voltage cables. They remain relatively stable dimensionally on thermal overloading. Their use in underfloor heating pipes or in self- cross-linking EPM or EDPM rubber articles is also common. The flameproofing of XL-PE with metal hydroxides is described in [197].

Cross-linking via silanol groups is also used in other polymers (e.g., vinyl acetate – acrylate dispersions [198], polyacrylates, or polyoxyalkylenes [199]) that are used as coatings, adhesives, or casting compounds.

Special Polymers. Unsaturated sil(ox)anes, in particular, have been proposed for copolymeric incorporation into standard polyolefins or polyacrylates. An important use is in raw materials for hard contact lenses, where a proportion of defined methacrylic-functional siloxanes [200] improves oxygen permeability. To enhance resistance to scratching, the surfaces of plastics are treated with silica-reinforced hydrolysates from, for example, $MeSi(OMe)_3$ (acrylic glass panes and consumer articles; polycarbonate spectacle lenses [201]). Polymers from short-chain or cyclic methylhydrosiloxanes, such as $[HMeSi(O)]_4$ [*2370-88-9*], with dicyclopentadiene and sometimes other diolefins, which are formed by platinum- catalyzed addition, are relatively new. They are recommended as nonstick, prehardened, impregnating resins for glass-fiber prepregs. The latter are laminated to

form carrier plates for printed electrical circuits [202]. The field of sil(ox)ane-modified organic polymers is described in detail in [203].

The rubber additive polysulfidesilane (Section 4.4.1 and Table 7) is both a coupling agent in mixtures with silicate fillers and a source of sulfur for rubber cross-linking. This unique, low-toxicity substance lowers the tendency to scorch (to undergo cross-linking too early), so that, for example, thick-walled tires for heavy-goods vehicles can be vulcanized without difficulty. In addition, it gives rubber a high reversion stability. In terms of quantity used, this is one of the most industrially important silanes [123].

Stabilizers. Silane polymer additives have a wide range of structures and effects. Incorporation of $(CH_3O)_3SiCH_2CH_2CH_2Cl$ [*2530-87-2*] or polysulfidesilane (see above) increases the thermal stability of filled EPDM rubber and of EPDM covulcanized with silicone rubber [204]. Phenylsil(ox)anols are suitable for flameproofing high-temperature polymers [205]. Sterically hindered phenolic or amine-containing alkoxysilane antioxidants bind migration-free to polymers and fillers owing to hydrolysis and condensation and thus ensure long-term stability [206]. Addition of (chlorine-free) organosilanes can delay the aging of PE insulating materials in a damp environment (treeing) [207]. Cyanacrylates adhere to deactivating surfaces (e.g., wood) more reliably after the addition of sila crown ethers [208].

6.5. Silanes in Catalysis

Silanes themselves are generally not catalytically active. However, their ability to form complexes with active metal compounds, whereby the catalyst system displays specific action, and the fixing of catalytically active centers to sil(ox)ane structures are of interest.

Donor Silanes. In the production of polypropylene with classical Ziegler – Natta catalysts the desired isotactic material is formed in unsatisfactory proportions. By using alkoxysilanes as external donors [209] an increase to $> 96\,\%$ isotactic material (heptane extraction) is achieved. The total catalyst requirement can be decreased to less than 1 : 20 000, so that separation from the polymer is unnecessary. Silanes $(CH_3O)_2SiRR^1$

with at least one sterically demanding group (e.g., R = cyclo-C_6H_{11}, R^1 = Me) [*17865-32-6*] have been shown to be the most effective donors. Bulk polymerization (Spheripol, Addipol, and Catalloy processes) and gas-phase processes (Unipol) are widely carried out by using these cocatalysts.

Siloxanes in Other Catalyst Systems. In high-temperature vulcanizing silicone rubbers, the Karstedt catalyst [60] is the most important platinum complex. It contains vinyl siloxane(s) as the complex-forming components, which give rise to the extremely high activity.

Mechanically tough, spherically uniform micro- and mesoporous particles can be produced by hydrolysis of suitable organofunctional silanes. They adsorb traces of metal or organic materials from (aqueous) solutions [210]. If they are coated with (noble) metal ions, highly active catalyst systems are formed [123]. Catalytically active groups can also be bonded to standard carriers via ambivalent silanes. For example, silane quats fixed on aluminosilicate (see Section 6.2) are excellent for the diproportionation of $MeHSiCl_2$ to MeH_2SiCl [*993-00-0*] or $MeSiH_3$ [*992-94-9*] [211].

In group-transfer polymerization [212] the reaction of α,β-unsaturated carbonyl monomers [e.g.,(meth)acrylates]is initiated by *O*-silylketene acetals and traces of certain anions at room temperature. This relatively new process works quasi-anionically and is a living polymerization, whose end products have a very narrow molecular mass distribution. They are used as paint additives.

6.6. Silanes for Use in Liquid Media

As a result of their high thermal stability, low pour points, and relatively flat temperature–viscosity curves, silicic acid esters of higher alcohols and peralkylated silanes have been proposed as high-performance lubricants for air- and spacecraft [213]. Phenylmethyltrisiloxanes are used as diffusion pump oils, and methylsilane glycol esters have been developed as brake fluids for auto racing [214]. For durability, modern car engines (specifically those made from light alloys) require corrosion inhibition on the interior metal walls. To prevent gel formation, various organofunctional silanes are added to the water–glycol cooling medium, whose pH is adjusted to slightly alkaline [215]. The addition of water-soluble organofunctional silanes to detergents [216] improves dirt removal from hard surfaces (rinsing agents) and lowers surface corrosion in enameled dishwashers, washing machines, and dryers. Effective wetting additives are of interest in agriculture, e.g., the glycol-modified trisiloxane $Me_3SiOSi(Me)[(CH_2)_3(OCH_2CH_2)_nOCH_3]OSiMe_3$ (n = ca. 8) [*87244-72-2* *]. It temporarily lowers the surface tension of water (at 0.1 % addition) to < 21 mN/m [217].

6.7. Silane Coupling Agents

Of all the organosilanes the silane coupling agents have resulted in the most important technological progress. From the early 1950s they were intensively developed, starting with the vinyl- and aminoalkoxysilanes, and they have influenced nearly all areas of technology, including the medical and analytical branches [114]. The field of silane coupling agents is covered by extensive literature [83, 84, 218, 219]. Characterization, synthesis, and some product-specific remarks on the use of coupling agents can be found in Chapter 4. Here, only the mode of action and the commercial products (Table 7) are mentioned.

Silane coupling agents are usually applied as prehydrolyzed, dilute (ideally 0.1–0.5 %, aqueous) solution, but also from the gas phase, by spraying, dipping, or direct mixing and (less often) in the form of primers (silane partial hydrolysates) on surfaces, fibers, or filler particles. Typical positively reacting inorganic [83] substrates are glass (fibers, hollow spheres), quartz (powder), (synthetic) silicas, wollastonite (calcium metasilicate), mica, kaolin, hydrated aluminum oxide, and among the metals, aluminum, steel, zinc, and copper (alloys) [220]. Additional complex-forming interactions of NH, SH, or COOH groups are believed to occur on metal surfaces.

The function Y must generally be adapted to the polymer type. Epoxy and aminoorganosilanes can be used quite universally. Reinforced or filled thermosets, thermoplastics, and elastomers become industrially and

economically more competitive by using silane coupling agents. Producers' leaflets give more detailed information on the areas of use and handling. The following is valid as a chemical basis for the coupling-promoting effect of organofunctional silanes with the structure $(RO)_3SiCH{=}CH_2$ or $(RO)_3SiR^1Y$ (Table 7) at interfaces between mineral or metallic substances and organic polymers. Silanols formed by optimal hydrolysis (see Section 3.1) of functional alkoxysilanes condense with the elimination of water, and strong MOSi bonds are formed with the hydroxyl containing substrate surface (M = Si, Al, Fe, etc.) and by the silane molecules with one another. A flexible siloxane intermediate phase, occasionally of varying thickness, must be formed, whose functional groups on the side facing the polymer can become bonded to the organic phase (covalent chemical bonding and interpenetration). The basic mechanisms and their effect on the solution of coupling problems are currently being investigated physicochemically [221]. Nevertheless, relationships between theory and activity are not always clear, so a test of practical application must be the deciding factor. Occasionally, silanes also act between different polymers. Compounds with fewer than three OR leaving groups can also be active but are rarely used in practice (to some extent for cost reasons, cf. Section 4.2), although their more hydrophobic intermediate phase increases their resistance to water.

Mode of Action. Reaction of the silanol groups of the intermediate phase with the OH groups of the inorganic substrate strongly alters the polarity and wettability of the latter, so that the polymeric binding agents, adhesives, or coatings, which are generally of low polarity, can spread and adhere better. As a result of the breakup of hydrogen bonds, penetration of the boundary layer by the diffusion of surrounding moisture is strongly hindered. Thus, consumer articles made of such fiber- or particle-reinforced composites (boats, tanks for liquids, sports articles) have a considerably increased lifetime. Often the mechanical properties can be clearly improved, even in the dry state, and the filler content increased (more economical at the same performance level), or areas of use and temperature ranges can be extended. The electrical values (dielectric strength, loss factor tan δ) are higher and less affected by the entry of water.

At the performance level attained today, improvements in activity can be achieved with new silane structures only in individual cases. Furthermore, restrictive laws in industrial nations are forcing deeper study of interaction phenomena in the combined use of known basic materials [219, 222]. Problems associated with the binding of mineral fibers and fillers in bulk plastics such as polyethylene or polypropylene [223], the incorporation of nonoxide fillers such as calcium carbonate (organotitanates, for example, are used here), and the reinforcement of high-temperature polymers, such as polycarbonates, polyimides, or polysulfones, have still not been solved satisfactorily. The standard silanes (Table 7) tend to yellow above 130 – 180 °C and bring about structural degradation. More recent developments include temperature-stable aromatic silanes containing carboxyl groups, for

example [138], multifunctional silanes [224], stable aqueous silane solutions free of alcohol groups, or "polymeric silanes" [225]. If economic considerations are not taken into account, cationic, silanized, finely divided filler particles could become important as additives for washing powders, particularly for hard water [226].

6.8. Silanes for Hydrophobic Surface Treatment

The modification of (mineral) surfaces with nonfunctionalized silanes has been studied to a similar extent as the use of silane coupling agents [227]. The aim of treatment (generally with inexpensive alkylchloro- or alkylalkoxysilanes) is the elimination of polar HOM groups, the removal of adsorbed moisture, or improved wetting by organic media. Hydrophilic surfaces become hydrophobic and lipophilic. This is particularly effective for particle fillers, increasing the maximum degree of filling or improving mechanical, electrical, and chemical resistance. Silanized silicas attract much interest for the thixotropic modification of certain epoxide resins and especially for improving the mechanical properties of silicone rubber. A compound produced by cocondensation of $Si(OEt)_4$ and $Me_3SiOSiMe_3$ is claimed to exhibit particularly good properties [228]. Another example of this use of silicon compounds is in the protection of building materials of all types (masonry, plaster, natural stone, concrete) against weathering. Alkylalkoxysilanes [229] or silicone microemulsions [230] are used for this purpose, for example. Water-repellent silanization is applied to glass instruments for chemical and medical use (e.g., ampules) or in the production of light bulbs. The solvent-, dirt-, and fat-repellent (soil release effect) action of alkylsilyl groups is surpassed by certain fluoroalkylsilanes (see Section 4.2).

Small quantities of volatile sil(ox)anes (e.g., $Me_3SiOSiMe_3$) are used in plasma chemical vapor deposition. The extremely thin polymeric silicon-containing layers formed, protect, for example, vapor-deposited aluminum headlight reflectors [231] and are used for the production of microstructures on electronic chips [232].

6.9. Analysis

The analysis of silanes and silicones is described in [233]. In liquid chromatography (reversed phase HPLC) of mixtures of substances [234], stationary phases of defined polarity that are attached by stable bonds to the silica gel carrier are produced by using silanes (frequently octyl or octadecyl, but also organofunctional types). These phases are suitable for the separation of pesticides, protein components, or optical isomers and for ion chromatography. Information is provided by equipment suppliers. The methods for protective silylation described in Section 6.1 enable the analysis of sensitive organic (natural) products as well as short-lived silanols by GC or GC/MS (Lentz technique). Even mineral analyses are possible by using Me_3Si derivatization [235]. Traces of silicon in the environment can be characterized by $Me_3SiOSiMe_3$ – catalyst [233], and surfaces contaminated with silicones can be cleaned by using the same mixture.

7. Toxicology and Environmental Aspects

The physiological action of silanes is strongly structure dependent. An overall description is not possible, so in this chapter only some important aspects are discussed.

Tetraorganosilanes are nontoxic, provided they do not contain any toxic organofunctional substituents. However, for silicon-functional compounds, toxicity must always be a consideration, particularly when they contain readily hydrolyzable groups. This leads to attack on the mucous membranes and the eyes, particularly at high volatility. Organohalosilanes can also cause severe skin irritation or corrosion, due to the hydrogen halides liberated on exothermic hydrolysis and the associated localized dehydration. In the case of contamination, washing with copious amounts of water is indispensable as a first-aid measure.

Organoalkoxysilanes do not generally exhibit pronounced toxicity; however, the formation of alcohol during hydrolysis must be considered. The widely used tetraethoxysilane has a TLV of 10 ppm. In comparison, the volatile compounds

$Si(OMe)_4$ (TLV = 1 ppm) and $HSi(OMe)_3$ [85, 236] are highly toxic. On inhalation, severe headache and visual disorders occur, which can lead to permanent blindness. Liver and kidney damage has also been reported [237].

Organofunctional silanes are generally considered of low toxicity. Depending on the substituents, special effects can also occur [188]. In the case of physiologically active silicon compounds (Section 6.2) these properties are specifically exploited.

Widely varying toxicity can be found in series of silanes that contain both organofunctional and silicon-functional groups. The combination of amino and alkoxy groups in particular, present in silatranes, for example [25, 238], leads to quite pronounced toxicity in some cases.

A considerable proportion of physiologically active organosilicon compounds is processed in-house to polymers that are of low activity or harmless. During production and transport, attention must be given to safe handling of the monomers. Depending on the vapor pressure, flammability, corrosivity, etc., suitable precautions must be taken, which are set out in safety data sheets. In industry, halosilanes should be stored in double-walled steel tanks under an inert gas. Laboratory quantities are kept in glass vessels; plastic containers are generally unsuitable.

8. Economic Aspects

The main source of monomeric organosilicon compounds is the crude silane mixture produced by the direct synthesis. Its production has increased greatly during the last decade. In 1977 the quantity of crude silane was 380 000 t; in 1985, 600 000 t; and in 1991, ca. 10^6 t. About 95 % of this is used for the production of silicones. This explains why the largest silicone producers are also the most important producers of monomeric silanes. In the United States, these companies are Dow Corning, General Electric, and Union Carbide; in Europe, Bayer (Germany), Hüls (Germany), Rhône-Poulenc (France), and Wacker-Chemie (Germany); in Japan, Shin-Etsu, Toray (joint enterprise with Dow Corning), and Toshiba (joint enterprise with General Electric). Most of these companies operate worldwide; the assignment by country is made by head office. There are also production units in the CIS and in China.

According to estimates, ca. 40 % of the world market is accounted for by the United States, 30 % by Western Europe, 15 % by Japan, and 15 % by the rest of the world. The total turnover in silicones was ca. 7.5×10^9 DM in 1991 [239]. Besides the crude silane mixture, essentially only trichlorosilane is used as a starting material for other silanes, especially organofunctional silanes; ca. 30 000 t of $HSiCl_3$ is estimated to have been used for this purpose in 1991. The high-value silanes obtained by this route (price per kilogram between 5 and 30 €; for special silanes, even higher) are used, among other things, as coupling agents, cross-linking agents, and for surface treatment. The world market for these applications was estimated to be 5×10^8 € in 1991 (United States 46 %, Europe 46 %, Japan 8 %) [240]. These types of silanes are produced also by other companies besides silicone producers, such as PCR Chemicals (United States), Degussa (Germany), and Chisso (Japan).

Other applications of monomeric organosilanes are of comparatively minor economic importance. Silylating agents, which are mainly used as reagents in the pharmaceutical industry, had a market volume of 38×10^6 € (ca. 7000 t) in 1991. Organosilanes used as catalyst components in polypropylene production had a turnover of ca. 7.7×10^6 € (400 t) in 1991.

1. Introduction

Nomenclature and Structure. The term silicones is used for compounds in which silicon atoms are linked via oxygen atoms, each silicon atom bearing one or several organic groups. In industrially important silicones, these groups are usually methyl or phenyl. The silicones are known as polyorganosiloxanes according to IUPAC rules.

The structure of the industrially important "methylsilicones" can involve the units listed in Table 1.

Polymer structures can be described by using the letters M, D, T, and Q to designate the monomer units. Linear silicone fluids are composed mainly of D units. The base polymers for silicone elastomers or silicone rubbers consist of D units that bear cross-linkable functional groups. The main structural feature of the highly branched silicone resins are T units, often combined with D units to make the resins more flex-

10.1002/14356007.a24_057

ible. Silicone resins can also contain Q and M units.

Table 1. Origin, functionality, and fields of application of silicone structural units

Starting compound	Structural unit		Application
	Symbol	Functionality	
$(CH_3)_3SiCl$ Monochlorotrimethylsilane	M	$H_3C-Si(CH_3)_2-O_{0.5}$ monofunctional	chain end in silicone fluids, trimethylsilyl protecting groups
$(CH_3)_2SiCl_2$ Dichlorodimethylsilane	D	$H_3C-Si(CH_3)-O_{0.5}$ $O_{0.5}$ difunctional	linear siloxane polymers, silicone fluids, rubbers, elastomers
CH_3SiCl_3 Trichloromethylsilane	T	$H_3C-Si(O_{0.5})-O_{0.5}$ $O_{0.5}$ trifunctional	silicone resins for paints, impregnating agents, masonry protection
$SiCl_4$ Tetrachlorosilane	Q	$O_{0.5}-Si(O_{0.5})-O_{0.5}$ $O_{0.5}$ tetrafunctional	silicone resins

General Properties. Silicones have many outstanding properties, which are described in detail for the individual product groups. In general, methylsilicones exhibit greater stability to high temperature, UV radiation, and weathering than organic polymers; marked surface-active behavior (low surface tension, high spreading power); good dielectric properties, as well as low temperature dependence of their physical properties.

2. Linear and Cyclic Polyorganosiloxanes

2.1. Production

Linear and cyclic polyorganosiloxanes are generally produced by reacting organodichlorosilanes with water. The mixture of oligomeric siloxanes arising from hydrolysis can be converted either entirely to cyclic siloxanes (e.g., octamethylcyclotetrasiloxane) or directly polymerized to linear polysiloxanes. A special case of the production of cyclic or linear oligomeric dimethylsiloxanes that has gained in importance is the methanolysis of dimethyldichlorosilane.

The most important chlorosilanes used industrially (> 90 % of the total) are the methylchlorosilanes. Other chlorosilanes that contain silicon-bound H, C_6H_5, CH_2=CH, or CF_3CH_2-CH_2 groups, either exclusively or in combination with methyl groups, are produced in smaller quantities. Chlorosilanes and siloxanes containing other organic ligands, such as C_2H_5 or $HOCH_2$, are not discussed in detail here because of their minor importance.

In the following sections, the processes of hydrolysis, methanolysis, polymerization, and polycondensation are described in more detail; the production of oligomeric polydimethylsiloxanes from dimethyldichlorosilane is used as an example throughout.

2.1.1. Hydrolysis

The complete hydrolysis of dimethyldichlorosilane leads to an oligomer mixture consisting of cyclic dimethylsiloxanes and hydroxyl-terminated dimethylsiloxanes:

$$n\,(CH_3)_2SiCl_2 + n\,H_2O \longrightarrow [(CH_3)_2SiO]_n + 2n\,HCl \quad n = 3, 4, 5, \text{etc.}$$

and simultaneously:

$$m\,(CH_3)_2SiCl_2 + (m+1)\,H_2O \longrightarrow HO[(CH_3)_2SiO]_m\,H + 2m\,HCl \quad m = 4 -> 100$$

Hydrolysis with a deficiency of water gives linear dimethylsiloxanes with terminal SiCl groups:

$$(n+2)\,(CH_3)_2SiCl_2 + (n+1)\,H_2O \longrightarrow Cl(CH_3)_2SiO[(CH_3)_2SiO]_n Si(CH_3)_2Cl + 2(n+1)\,HCl$$

Complete hydrolysis with excess water is carried out continuously in the liquid phase with ca. 25 % hydrochloric acid or in the gas phase at ca. 100 °C. Liquid-phase hydrolysis gives cyclic and linear oligomeric dimethylsiloxanes in the approximate ratio 1: 1 to 1: 2, depending on reaction conditions, together with ca. 30 % hydrochloric acid. The hydrochloric acid can be reacted with methanol to produce chloromethane,

which is used for producing methylchlorosilanes in the Rochow synthesis (→ Silicon Compounds, Organic, Chap. 2.1.) [1–4] (chlorine recycling).

The ratio of cyclic to linear dimethylsiloxanes and the chain length of the linear oligomers can be varied over a relatively wide range by means of hydrolysis conditions. For example, rapid removal of hydrochloric acid from the reaction mixture by neutralization leads almost exclusively to short-chain siloxanediols. Cyclic siloxanes represent up to two-thirds of the reaction product if prolonged contact with HCl occurs. The tetramer octamethylcyclotetrasiloxane is the predominant cyclic siloxane.

Control of the hydrolysis reaction to give predominantly cyclic or linear oligomeric dimethylsiloxanes is important because high-molecular mass polydimethylsiloxanes are produced both by equilibrating polymerization and by polycondensation. The preferred starting materials for equilibrating polymerization are cyclic siloxanes, while polycondensation is only possible with hydroxyl-terminated oligomers.

The hydrolysis process can also be used to produce organosiloxanes modified with functional groups. For example, the reaction of a mixture of dimethyldichlorosilane, methylhydrogendichlorosilane, and trimethylchlorosilane with excess water affords a trimethylsilyl end-stopped linear polymethylsiloxane with a random distribution of dimethylsiloxy and methylhydrogensiloxy units. The ratio of the two difunctional methylsiloxane units in the mixture can be varied at will. The average chain length of the siloxanes formed decreases with increasing trimethylchlorosilane content in the silane mixture.

$$n\,(CH_3)_2SiCl_2 + m\,CH_3(H)SiCl_2 + 2(CH_3)_3SiCl + (n+m+1)\,H_2O \longrightarrow (CH_3)_3SiO[(CH_3)_2SiO]_n[CH_3(H)SiO]_m Si(CH_3)_3 + 2(n+m+1)\,HCl$$

The hydrolysis product mixture is influenced to a certain degree by the addition of organic solvents. This method is especially useful for obtaining siloxanes that contain silanol groups and silicone resins (see Section 5.2).

Figure 1 shows a schematic of the hydrolysis process.

2.1.2. Methanolysis

The methanolysis process for the production of siloxanes from dimethyldichlorosilane allows direct recovery of the chlorine from methylchlorosilanes as chloromethane. The silane reacts with methanol to give oligomeric dimethylsiloxanes and chloromethane. Two variants of this process exist, one of which leads to linear hydroxyl end-stopped oligomeric siloxanes, whereas the other affords mainly cyclic siloxanes. In the former, siloxanes are removed from the bottom of the reaction column, and the lower-boiling cyclic compounds in the overhead are returned to the process; in the latter, volatile cyclic oligomers are removed continuously from the reaction mixture by distillation.

In both cases the methanolysis plants are operated in association with methylchlorosilane production. Figures 2 and 3 show how methanolysis or hydrolysis of dimethyldichlorosilane is integrated with the Rochow synthesis and the plants for further processing.

Methanolysis occurs according to the following overall equations:

$$n(CH_3)_2SiCl_2 + 2n\,CH_3OH \longrightarrow HO\,[(CH_3)_2SiO]_nH + 2n\,CH_3Cl + (n-1)H_2O$$

$$n(CH_3)_2SiCl_2 + 2n\,CH_3OH \longrightarrow [(CH_3)_2SiO]_n + 2n\,CH_3Cl + n\,H_2O$$

Figure 2. Integration of the hydrolysis or methanolysis of dimethyldichlorosilane via intermediate linear dimethylsiloxanes in silicone production

Dimethyl ether formed as a byproduct is purged from the process or allowed to react with hydrochloric acid to form chloromethane, depending on the process variant.

If the synthesis and methanolysis of dimethyldichlorosilane are regarded as a single process unit, then overall, dimethylsiloxane is formally produced from silicon and methanol, with water as the only byproduct. Recycling of chlorine as chloromethane avoids HCl waste, making silicone production cleaner and more efficient.

Rochow synthesis:

$$n\,\mathrm{Si} + 2n\,\mathrm{CH_3Cl} \longrightarrow n\,(\mathrm{CH_3})_2\mathrm{SiCl_2}$$

Methanolysis:

$$n\,(\mathrm{CH_3})_2\mathrm{SiCl_2} + 2n\,\mathrm{CH_3OH} \longrightarrow [(\mathrm{CH_3})_2\mathrm{SiO}]_n + 2n\,\mathrm{CH_3Cl} + n\,\mathrm{H_2O}$$

Overall:

$$n\,\mathrm{Si} + 2n\,\mathrm{CH_3OH} \longrightarrow [(\mathrm{CH_3})_2\mathrm{SiO}]_n + n\,\mathrm{H_2O}$$

2.1.3. Cyclization

Pure cyclic siloxanes are produced by cyclization. Octamethylcyclotetrasiloxane and decamethylcyclopentasiloxane are major industrial products, which are either marketed as such or used for the production of polydimethylsiloxanes. Cyclization is performed by heating the hydrolysis or methanolysis mixture with potassium hydroxide. Process aids are used to prevent polymerization of the siloxanes to high-viscosity liquids. Potassium hydroxide catalyzes an equilibration reaction in which the Si–O–Si bonds are cleaved and reformed. During the reaction, the lower-boiling octamethylcyclotetrasiloxane and decamethylcyclopentasiloxane are distilled continuously from the reaction mixture. The siloxanes are constantly reformed to maintain the equilibrium until the siloxane mixture is completely converted to the desired cyclic siloxanes.

Figure 3. Integration of the hydrolysis or methanolysis of dimethyldichlorosilane via intermediate cyclic dimethylsiloxanes in silicone production

2.1.4. Polymerization

Linear polyorganosiloxanes can be prepared from cyclic organosiloxanes by equilibrating ring-opening polymerization, which is promoted by both anionic and cationic catalysts [5,6]. Octamethylcyclotetrasiloxane is the preferred starting material. Other siloxanes are used for chain end-stopping or for producing copolymers.

Anionic polymerization with alkali-metal hydroxide catalysts is of industrial importance. The catalytic activity decreases in the series Cs > Rb > K > Na > Li [7]. KOH is the most common catalyst. Rapid polymerization is observed above 140 °C on adding as little as a few ppm KOH, e.g., as a suspension in octamethylcyclotetrasiloxane. The polymerization mechanism involves initial formation of potassium siloxanolate, which then catalyzes chain growth and equilibration via cleavage of Si – O – Si bonds.

The polymerization reaction leads to an equilibrium mixture of linear polysiloxanes and ca. 15 – 18 wt % cyclic siloxanes. The average chain length of the linear polysiloxanes is controlled by the ratio of end groups to D units in the polymerization mixture. Various substances (called

regulators) added during polymerization determine the end groups. A Poisson distribution of molecular mass is obtained.

For example, hydroxyl-terminated polydimethylsiloxanes are formed in the presence of water. The average molecular mass depends on the amount of water added. If trimethylsiloxy-containing siloxanes (e.g., MD_2M) are added to the polymerization mixture then trimethylsilyl-terminated polymethylsiloxanes are formed.

Cation- complexing additives such as poly(ethylene glycol), crown ethers, methyl ethyl ketone, dimethylformamide, and dimethyl sulfoxide accelerate the reaction [5, 8] by promoting the dissociation of inactive silanolates:

After the molecular mass distribution has reached equilibrium, the catalyst must be deactivated. Numerous deactivation methods have been described. KOH is generally neutralized with phosphoric acid or chlorosilanes. Careful neutralization is essential for the stability of the polymer, since both alkaline and acid residues lead to degradation of the siloxane chain by depolymerization. After neutralization, the volatile low molecular mass constituents (mostly cyclic compounds) are removed by distillation and recycled to the polymerization process.

Cationic polymerization of cyclosiloxanes is carried out with strong protic or Lewis acids. Industrially important catalysts are perfluoroalkanesulfonic acids or sulfuric acid [5, 6]. The reaction mechanism has not yet been fully elucidated.

Another method of cationic polymerization employs acidic solids such as ion-exchange resins and acid-activated silicates as catalysts. Cationic polymerization also leads to an equilibrium mixture of linear polysiloxanes.

2.1.5. Polycondensation

Linear oligomeric dimethylsiloxanes from the hydrolysis or methanolysis process can be polymerized by polycondensation. This process requires the use of high-purity dimethyldichlorosilane if strictly linear siloxane polymers are to be produced, since purification of the siloxanediols by distillation is not possible.

Polycondensation is carried out as a batch or continuous process in the presence of acid catalysts, preferably polychlorophosphazenes $(PNCl_2)_x$ [9–11]. The water produced in the reaction must be removed. When the desired chain length is reached, the catalyst is deactivated with ammonia or an amine [12, 13].

Polycondensation of siloxanediols proceeds very rapidly at elevated temperature under vacuum (Fig. 4, curve a). In the presence of a short- chain, $R(CH_3)_2SiO$-terminated dimethylsiloxane ($R = CH_3$, $CH{=}CH_2$, H) that regulates the chain length via equilibration, a combination of polycondensation and slower equilibrating polymerization occurs, and the system therefore passes through a marked viscosity maximum (Fig. 4, curve b). With a siloxanol as chain-length regulator, the final viscosity is reached more quickly (Fig. 4, curve c) because only condensation steps occur.

Figure 4. Polycondensation – equilibration of siloxane diols
a) $HO[(CH_3)_2SiO]_nH$; b) $HO[(CH_3)_2SiO]_nH + R(CH_3)_2SiO[Si(CH)_2O]_xSi(CH_3)_2R$;
c) $HO[(CH_3)_2SiO]_nH + R(CH_3)_2SiO[Si(CH_3)_2O]_xH$
$R = CH_3$, $CH = CH_2$

$R(CH_3)_2SiO$-terminated polydimethylsiloxanes can be obtained by polycondensation

Table 2. Polymerization processes

Starting material	D_4	D_4	$HO[(CH_3)_2SiO]_nH$
Catalyst	KOH	H_2SO_4	$(PNCl_2)_x$
Amount of catalyst, ppm	5 – 20	100 – 1000	5 – 200

and equilibration of the siloxanediols with $R(CH_3)_2$ SiO-terminated dimethylsiloxanes or by polycondensation of the siloxanediols followed by silylation of the silanol end groups with hexaorganodisilazanes, $R(CH_3)_2SiNHSi(CH_3)_2R$, for example.

2.1.6. Industrial Production of Linear Polysiloxanes

For small-volume products, the polymerization of oligomeric siloxanes is carried out in stirred vessels; batches up to 15 t are readily controllable. Larger quantities are produced in continuous plants (Fig. 5).

Depending on the type of polymerization reaction, the following process steps:

1) Purifying and drying the starting materials
2) Catalyst and regulator metering
3) Establishing equilibrium and condensation
4) Neutralization
5) Oligomer removal and distillate recycling

pose different technical requirements, which are summarized in Table 2.

When the variants are considered, five process designs for performing the polymerization have essentially prevailed:

1) Single-stage polymerization vessel
2) Stirred-tank cascade
3) Screw extruder reactor
4) Cell reactor (tubular reactor with spiral stirrers that generate approximately plug flow)
5) Solid (catalyst) reactor

2.2. Polydimethylsiloxanes

Linear polydimethylsiloxanes are the most important industrial polysiloxanes. The polymers are classified according to their viscosity (i.e., average chain length) and the nature of the end groups. The most important polymer types characterized by their end groups are listed in Table 3.

The endgroups determine the use. For example, trimethylsilyl-terminated polydimethylsiloxanes are typical silicone fluids. Hydroxy- and vinyl-terminated polymers find major application in silicone rubbers.

Table 3. Types of polymer

End group	Structure
Methyl	$(CH_3)_3Si-O-[(CH_3)_2Si-O-]_x-Si(CH_3)_3$
OH	$HO-(CH_3)_2Si-O-[(CH_3)_2Si-O-]_x-Si(CH_3)_2-OH$
Vinyl	$CH_2{=}CH-(CH_3)_2Si-O-[(CH_3)_2Si-O-]_x-Si(CH_3)_2-CH{=}CH_2$
H	$H-(CH_3)_2Si-O-[(CH_3)_2Si-O-]_x-Si(CH_3)_2-H$

2.3. Siloxane-Based Copolymers

Siloxane copolymers containing other siloxy groups in addition to dimethylsiloxy groups are used to obtain special properties. With a few exceptions, these copolymers have the general structure

$$R(CH_3)SiO[(CH_3)_2SiO]_x[(R^1)(R^2)SiO]_ySi(CH_3)_2R$$

The substituents R, R^1, and R^2 can be identical or different. The most important D units are:

R = C_2–C_{14} alkyl

Table 4. Important types of silicone fluid

Structural formula	Brief designation

The copolymers are usually produced by copolymerization of the appropriately substituted cyclosiloxanes and D_4 under equilibrating conditions. In this way, the various D groups are distributed randomly along the polymer chain. Exceptions are block copolymers that are produced by anionic polymerization under nonequilibrating conditions.

Polymers with trifluoro groups are also prepared by the kinetically controlled polymerization of $[CH_3(CF_3CH_2CH_2)SiO]_3$, since 96 wt % cyclics are formed at equilibrium [14].

For example, polydimethyl – polydiphenyl block copolymers are produced by stepwise polymerization of D_3 and $(DPh_2)_3$ with Li- containing bases in tetrahydrofuran. The resulting

block copolymers have a twophase morphology and elastomeric properties.

3. Silicone Fluids

The structure of linear silicone fluids can generally be described by the composition MD_xM ($x = 2-4000$).

Silicone fluids are distinguished from common organic fluids by a number of unique properties:

1) Good thermal stability (150 – 250 °C)
2) Good low-temperature performance (<−70 °C)
3) Strong hydrophobicity
4) Excellent release properties
5) Antifriction and lubricating properties
6) Pronounced surface activity
7) Good dielectric properties
8) Very good damping behavior
9) Good radiation resistance
10) High solubility of gases
11) Physiological inertness
12) Low temperature dependence of physical properties

These properties can be modified over a wide range by varying the organic substituents. The most important silicone fluids are listed in Table 4.

3.1. Methylsilicone Fluids

The most important silicone fluids are the methylsilicone fluids (polydimethylsiloxanes, PDMS). Silicone fluids exhibit a chain-length distribution. The average chain length largely determines the viscosity. Low molecular mass volatile constituents are removed during production, which increases the flash point of the final product. Fluids with viscosities ranging between 1 and 10^6 mPa · s are commercially available.

The most important physical properties of polydimethylsiloxanes are listed in Table 5, which shows that the physical properties of silicone fluids depend on the molecular mass only up to a certain degree of polymerization. With increasing molecular mass, they reach a limiting value.

3.2. Methylphenylsilicone Fluids

Methylphenylsilicone fluids exhibit higher thermal stability, better low-temperature properties, more powerful solvent action for organic substances, and better lubricating properties than PDMS. Their radiation resistance is also particularly high. The physical properties of methylphenylsilicone fluids of high and low phenyl content are listed in Table 6.

Table 6. Physical properties of methylphenylsilicone fluids

	Baysilone fluid PN 200 ∗	Baysilone fluid PH 1000 ∗

3.3. Other Types of Silicone Fluids

Methylhydrogensilicone fluids have silicon –hydrogen groups that react with protic compounds with the formation of hydrogen. Inorganic and organic surfaces having reactive groups, OH or NH_2 groups (such as glass), for example, can be modified. As a result these surfaces acquire completely new properties (see Section 3.6).

Fluorosilicone fluids have gained importance due to their outstanding low-temperature lubricating properties, low solubility in mineral oils, and the unique properties of fluorosilicone-treated surfaces.

Methylalkylsilicone fluids containing C_2 – C_{14} alkyl groups have better lubricating properties than pure PDMS. Like the methylphenylsiloxanes, they have better compatibility with organic substances (e.g., solvents or organic paint systems).

Figure 6. Temperature dependence of the viscosity of silicone fluids compared with mineral oils

3.4. Properties

Viscosity and Molecular Mass. The relation between the viscosity and the molecular mass of PDMS can be expressed approximately by the equation

$$M = \frac{464 \cdot (\eta_{25})^{0.825}}{2 + 0.0905 \cdot (\eta_{25})^{0.555}}$$

Other equations that are applicable to specific molecular mass ranges are given in [15, 16].

Determination of the molecular mass of linear and cyclic polymers from the intrinsic viscosity $[\eta]$ (in mL/g) by means of the formula $[\eta] = K \cdot M^{\alpha}$ is described in [17].

Temperature Dependence of Viscosity. An important property of silicone fluids is the small dependence of the viscosity on temperature, compared to other fluids. The viscosity of PDMS as a function of temperature is shown in Figure 6, which includes mineral oils for comparison.

The relatively low viscosity of silicone fluids at low temperature and the low pour point are important in many applications. The viscosity–temperature coefficient (VTC)

$$\mathrm{VTC} = 1 - \frac{\nu^{99\,^\circ\mathrm{C}}}{\nu^{38\,^\circ\mathrm{C}}}$$

which is frequently reported in the technical literature, is ca. 0.6 for silicone fluids.

As also shown in Figure 6, increasing the phenyl content (phenylsilicone fluids PH 1000) increases the VTC, and the viscosity–temperature behavior approaches that of mineral oils.

Mixture Viscosity. Formulas are available for determining the viscosity of a mixture of two silicone fluids [18]. Silicone fluid manufacturers provide this information in mixture diagrams (Fig. 7).

The required mixing ratio can be determined with the aid of the mixture diagram. For example, if a fluid of viscosity 6000 mPa · s is to be blended at 25 °C from a silicone fluid with viscosity of 1000 mPa · s and a silicone fluid with a viscosity of 12 500 mPa · s, the value 1000 mPa · s is marked on the left-hand side and the value of 12 500 on the right-hand side, and the two values are joined by a straight line. The intersection of this straight line with a line drawn parallel to the x-axis through the value of 6000 mPa · s indicates the mixing ratio on the x-axis, in this case 70 % silicone fluid of viscosity 12 500 mPa · s and 30 % silicone fluid of viscosity 1000 mPa · s.

Figure 7. Viscosity adjustment by blending

Newtonian Behavior and Pseudoplasticity. Silicone fluids of low or medium viscosity exhibit Newtonian behavior up to high shear rates (see Fig. 8). However, high-viscosity silicone fluids have lower Newtonian plateaus and show pseudoplastic behavior at lower shear rates. If the viscosity is decreased by raising the temperature, the pseudoplastic behavior begins at a higher shear rate.

Compressibility. The very high compressibility of polydimethylsiloxanes is apparent in the compressibility coefficient of 100×10^{-11} m^2/N. Methylphenylsilicone fluids have lower values of ca. 60×10^{-11} m^2/N, whereas mineral oils exhibit coefficients of ca. 50×10^{-11} m^2/N.

Thermal Properties. Thermal conductivities and specific heats of various silicon fluids are listed in Tables 5 and 6. Both values are nearly independent of temperature.

The thermal stability of dimethylsilicone fluids is very high. Little change is observed in the physical properties even after prolonged exposure to temperatures of 150 – 200 °C in air. Methylphenylsilicone fluids are stable at temperatures as much as 50 °C higher. In inert atmosphere or under vacuum the thermal stability is even higher.

At higher temperature, atmospheric oxygen leads to cleavage of the organic groups and consequently to gelling by cross-linking. By contrast, prolonged heating in a closed system in the absence of oxygen causes chain scission and a decrease in viscosity. These processes are very dependent on the nature of the contacting surfaces and the presence of catalyst traces or impurities.

Figure 8. Flow behavior of silicone fluids at 25 °C

Solubility. The PDMS and methylphenylsilicone fluids are highly soluble in aliphatic, aromatic, and chlorinated hydrocarbons, as well as in most ethers, esters, and higher alcohols. They are insoluble in water, methanol, and ethylene glycol. The solubility in organic solvents decreases with increasing viscosity of the polymer. PDMS with viscosities >20 mPa·s exhibit only limited solubility in acetone, ethanol, butanol, and isopropanol. PDMS of different viscosities can be mixed, but PDMS and methylphenylsilicone fluids are immiscible.

The solubility of gases in polydimethylsiloxanes is considerable. Thus, 1 g of silicone fluid dissolves 0.19 mL of air, 0.17 mL of N_2, or 1 mL of CO_2 at room temperature.

Interfacial Properties. Silicone polymers exhibit low surface tension: ca. 20 mN/m for

polydimethylsiloxanes, and ca. 25 mN/m for methylphenylsiloxanes (see Tables 5 and 6).

Since most solids have surface tensions > 20 mN/m, silicone fluids readily form surface films. Exceptions are polyolefins and polytetrafluoroethylene, whose surface tensions are also low. The interfacial tension of polydimethylsiloxane against air and water is listed in Table 7. A water drop on siliconized glass has a contact angle of 80 – 110°, which decreases on prolonged contact due to changes in the state of orientation of the silicone film [19]. Four different states are observed. The spreading of silicone fluids on water leads to ordered systems [20].

Table 7. Interfacial tension σ of polydimethylsiloxane (140 mm^2/s) against air and water at different temperatures [18]

Temperature, °C	σ, mN/m	
	Against air	Against H_2O
10	22.9	28.5
20	22.2	29.5
30	21.5	30.5
40	20.9	32.5
50	20.2	33.0
90	17.5	

3.5. Formulation

Some properties of polyorganosiloxanes can be particularly advantageous in certain formulations. Silicone fluid-in-water emulsions are preferred forms for applying thin films or for metering very small amounts. Silicone fluid emulsions are used, for example, as release agents, for impregnating surfaces, for water repellency treatment, in antifriction applications, and as antifoam agents. Emulsions are generally sold as 10 – 35 % concentrates, which are diluted to usually less than 1 %, sometimes only a few parts per million, before use. Silicone microemulsions, some of which are transparent, are aqueous systems with silicone particle sizes of 10 – 80 nm [21]. For certain applications, silicone fluids are formulated with silica or other consistency-increasing additives such as metal soaps, polytetrafluoroethylene (PTFE), boron nitride, and ureas to make pastes (see Section 3.6).

3.6. Applications

The characteristic properties of silicone fluids are exploited in numerous applications [22]. Thus, because of their high thermal stability and good low-temperature performance, they are used as *heat-transfer media* in heating circuits in the chemical, petrochemical, pharmaceutical, and food industries and in solar power plants, and as *refrigerants* in cryostats, freeze dryers, and climate simulation plants. Their low surface tension leads to use as *release agents* in the processing of plastics and rubber articles.

Silicone fluids, especially functional copolymers with Si – H or Si – OH groups, spread on surfaces to form oriented films with their hydrophobic organic groups aligned opposite to the phase boundary of the substrate. These functional copolymer fluids have many uses as additives in water-repellent *polishes*, as *waterproofing agents* for textiles, and as *protective coatings* for building materials. Their high water vapor permeability is a particular advantage, permitting good ventilation of water vapor while largely preventing the entry of liquid water.

Because of their surface activity, polydimethylsiloxanes are used as *antifoams* in aqueous systems, in petroleum processing, and in laundry detergents. Special formulations with highly dispersed silica are effective antifoams even in the part-per-million range. In human and veterinary medicine, siloxane antifoams are used as *antiflatulent* agents. The antifriction properties of polydimethylsiloxanes make them useful as *lubricants* (e.g., for films, yarn, medical articles, wine corks, and fillers). Special silicone fluids that dissolve spermicides of the Nonoxinol-9 type can be used as prophylactic coatings for condoms. Silicone fluids are increasingly important as *dielectric coolants* for transformers and rectifiers because of their flame resistance [23], resistance to ageing, material compatibility, and physiological inertness. These properties are also important for use as *power transmission fluids* in viscous and fan couplings [24] and as *hydraulic* and *damping fluids* in shock absorbers, railway buffers, and vibration insulation systems, at both high and low temperature. The more advantageous lubricating properties of siloxanes compared to pure organic products in the temperature range from less than

$-20\,°C$ to $>150\,°C$ have led to their use as *lubricants*. The greases or pastes obtained by incorporating consistency improvers exhibit a particularly good lubricating behavior when the base fluids are modified by phenyl, long-chain alkyl, or fluoro groups. They are used chiefly for lubricating electric motors, motor bearings of furnace blowers and ventilators, pump bearings for liquid gases, and machine bearings for low-temperature operation. Flexure-stable silicone fluid pastes are used as *embedding compounds* for glass-fiber cables in communication engineering. Since silicone fluids have a good dissolving power for organic vapors, they can be used as *absorbents* for organic vapors of low water solubility in off-gas purification. Modified silicone fluids are used as *paint additives* to influence the leveling or to obtain special finishes (e.g., hammer effect). Their tolerance by the skin and their physiological inertness [25] make silicone fluids suitable as additives for *ointments* and *cosmetic preparations*.

4. Silicone Rubbers and Elastomers

4.1. General Properties

Silicone polymers exhibit low glass transition and equilibrium melting temperatures, weak intermolecular interactions, and high chain mobility. These properties make them highly suitable for use in rubbers.

Silicone polymers can incorporate a variety of functional groups as potential cross-linking points. The position (exclusively chain ends, or along the polymer chain) and the content of these functional units can be readily varied. Together with the wide range of polymers and their compound viscosities these different cross-linking systems lead to many applications.

The development of silicone elastomers is reviewed in [26–28]. Specialized rubbers with unique properties such as low-temperature flexibility down to $-70\,°C$ according to DIN 53548 (phenyl, ethyl) [29], oleophobicity and solvent resistance (fluoroalkyl, cyanoalkyl), or higher surface tension (polyether) are obtained by replacing the methyl groups with other organic groups.

Curing (vulcanization) converts unvulcanized silicone compounds into silicone rubbers/elastomers. Unlike other rubber polymers, unfilled silicone rubbers achieve only low mechanical strengths when cured. Adequate strengths are only obtained by incorporating reinforcing fillers. High surface area silicas are used almost exclusively for this purpose.

The stress – strain curves of filler-free siloxane networks at small deformations can be well described by the semi-empirical Mooney – Rivlin equation [30, 31]. The ultimate strength of silicon elastomers is determined by the attainable average chain length between cross-links [32]. The Einstein – Guth – Gold equation is also used to describe filled silicone elastomers [33].

4.2. Rubber Compounds

Reinforcing Fillers. Whereas carbon black is most commonly used to reinforce standard organic elastomers, the best reinforcing fillers for silicones are finely-divided silicas. Both pyrogenic and precipitated silicas with BET surface areas of $150-400\,m^2/g$ are used. These silicas have average primary particles of only 7 – 30 nm, which, however, are present in silicone compounds as larger aggregates [34]. Transparent silicone elastomers can be produced with silica fillers because of the small primary particle size.

The tensile strength of silicone elastomers reinforced with high surface area silicas can be as much as 50 times that of unfilled systems, reaching values of up to 12 MPa. Common organic elastomers are significantly stronger and can attain tensile strengths of 20 – 25 MPa.

The silica filler is normally added to the silicone polymer during formulation. However, precipitated silicas can also be generated in situ in solvents [35] or even directly in the rubber polymer from orthosilicate esters [36, 37]. Silica fillers cause a large increase in the viscosity of the formulated rubber [38]. Fillers also influence the low-temperature crystallization rate of the elastomer [26].

Reinforced silicone elastomers usually contain 5 – 38 wt % silica filler. An increase in the viscosity is observed above 2 wt % filler [34]. A higher filler content, like a higher cross-link density, leads to an increase in both the modulus and the hardness of cured rubbers. Increasing the filler content or filler surface area also

raises the tensile strength, while at the same time causing a deterioration of the relaxation behavior of the polymer network. The tensile strength reaches a maximum at filler concentrations of 25 – 30 wt % [34]. The relaxation behavior is influenced by the inflexible filler – filler network, which hinders reversible deformation of the polymer. The stress – strain curves of filled elastomers show a large reduction in stress and hardness after the first deformation (Mullin effect: breakdown of the solid – solid interactions) [39]. A significant increase in the storage modulus is observed above 20 wt % filler. At this filler concentration, known as the percolation point, the silica aggregates meet and interpenetrate the entire polymer network [40].

Inert Fillers. Lower surface area, "inert" fillers are used for cost reduction and for adjusting certain properties. Common inert fillers are quartz powders, diatomaceaous earth, siliceous and other chalks, talcs, micas, calcium or zirconium silicates, and alumina trihydrate. Inert fillers can be used to modify the stress – strain behavior. Substitution of silica by inert fillers leads to a lower hardness and a decrease in the modulus. Treatment of inert fillers with special silane coupling agents can partially compensate for this effect [41].

Inert fillers increase the thermal conductivity of the elastomers [42,43]. Electrically conducting elastomers can be produced by addition of special furnace blacks or other conductive materials (carbon fibers, metal powders) [44,45].

Process Aids. Pyrogenic silicas used in reinforcing silicone elastomers have a pronounced thickening action due to hydrogen bonds between the filler aggregates. Three-dimensionally cross-linked structures, formed in the nonpolar silicone polymer matrix, hinder flow even at low concentration (> 2 wt %). At high filler concentration (ca. 25 wt %), such as are necessary for optimal reinforcement, the viscosity is so high that the compounds can no longer be remilled. Process aids are used in silicone rubber manufacturing to reduce the viscosity. These process aids react to form a hydrophobic filler surface and thereby restrict filler – filler interactions. Silylating agents such as silylamines and silylacetamides [46] are particularly effective. Hexaalkyldisilazanes are preferred.

Silylation decreases the proportion of surface-bound rubber (gel content or bound rubber) and prevents hardening and viscosity increase on storage (crepe hardening). However, hydrophobic fillers are less strongly reinforcing [47]. Siloxanediols and alkoxysilanes are used as process aids when a higher pseudoplasticity is required. This applies to solid rubbers, for which stability under load is necessary for processing (e.g., extrusion).

As an alternative to treatment of fillers during rubber manufacture, pretreated fillers can also be used.

Stabilizers. Specific performance properties of silicone elastomers, such as resistance to hot air, chemicals, or fire, can be improved by using additives. Generally, very small quantities (0.001 – 10 wt %) are required. Metal oxides; salts of iron, titanium, zirconium, cesium, nickel, copper, cobalt, or manganese; or carbon blacks are suitable for inhibiting the cross-linking by hydroxyl radicals produced in hot air at > 220 °C [48,49].

The action of water, acids, or bases can lead to depolymerization of the siloxane polymer network [50]. Stabilizers against these agents are alkaline-earth silicates, certain amphoteric hydroxides, and specific organic polymers [51,52].

Silicone elastomers can be protected from continued burning following ignition by addition of conventional flame retardants such as haloaromatics with Sb_2O_3 [53] or $Al(OH)_3$ with zinc borate [54,55]. A method of flame retardation specific to silicones is the use of platinum (10 – 60 ppm), TiO_2 [56], Fe_2O_3, or carbon black, and certain nitrogen compounds [57], which under the action of fire result in ceramization of the surface and reduced depolymerization [58,59].

4.3. Rheology

Both the viscosity and its dependence on shear rate are important in the processing of silicone rubber compounds. The requirements of various rubber processing methods can be readily met because of the large range of silicone polymer viscosities and the different methods of hydrophobic filler treatment [60].

Maximum strength is achieved with high-viscosity polymers and small primary particle size silica fillers. In the case of pyrogenic silicas, the best fillers are those with the highest surface area [34].

Deviations from Newtonian flow behavior can be adjusted for the various silicone rubbers by means of the filler surface area, filler dispersion, and the filler surface treatment. Thus rubbers with weak (two- component RTV) or strong (HTV) shear thinning are available, as well as pumpable liquid silicone rubbers (LSR) and rubbers with thixotropic behavior (one- component RTV).

4.4. Curing Systems

4.4.1. Radical Curing with Peroxides

Silicone rubbers are cross-linked at high temperatures with peroxides but not with sulfur. Both peroxides common in the rubber industry and specific to silicone processing are used. Cross-linkable silicone polymers must contain unsaturated groups in sufficient amounts. Preferred polymers contain 0.03–2 wt % methylvinylsiloxy groups. The concentration of methylvinylsiloxy groups determines the cross-link density and thus important elastomeric properties such as elongation. The vinyl group distribution in the polymer can be determined by means of ^{29}Si NMR spectroscopy [61].

Four groups of peroxides are commonly used industrially: dialkyl, peroxyketal, diaroyl, and alkyl aroyl. The peroxides used preferably are:

Dicumyl peroxide
tert-Butyl peroxybenzoate
tert-Butyl cumyl peroxide
2,5-Dimethylbis(2,5-*tert*-butylperoxy)-hexane
Bis(2,4-dichlorobenzoyl) peroxide
Bis(4-methylbenzoyl) peroxide.

Dialkyl peroxides cross-link mainly via the vinyl groups [62, 63]. The more reactive diaroyl peroxides are less specific and give the higher cure rates required for pressureless curing.

The structure of the polymer cross-links has been elucidated by ^{29}Si NMR spectroscopy and by depolymerization to low-molecular weight units in several cases [62]. Nonspecific peroxides cross-link via both methyl and vinyl groups, forming mostly propylene and butylene bridges, but also a few ethylene bridges, between polymer chains [63, 64]. Diaroyl peroxides can react with the vinyl silyl groups to form ester and ether groups [65]. The major side products of peroxide decomposition are acids.

The cross-link yield with low-vinyl content polymers can be increased by using co- cross-linkers such as triallyl isocyanurates or acrylates [66].

4.4.2. Hydrosilylation Curing

The highly selective hydrosilylation curing process is becoming increasingly important for the vulcanization of silicone rubbers. The cross-linking reaction is based on the addition of Si–H groups to C=C double bonds (see → Silicon Compounds, Organic, Chap. 2.4.). Usually, long- chain polydimethylsiloxanes containing two or more vinyl groups are reacted with short-chain methylhydrogensiloxanes (cross-linkers) in the presence of metal catalysts according to the equation:

$$\equiv Si-H + CH_2=CH-Si\equiv \xrightarrow{Pt} \equiv Si-CH_2-CH_2-Si\equiv$$

Preferred catalysts are platinum compounds. Concentrations as low as a few ppm platinum lead to adequate curing rates.

Hydrosilylation curing, unlike cross-linking by peroxides, produces no decomposition products. The reaction rate can be varied over a wide range by means of the catalyst concentration and by using inhibitors (e.g., 2-methyl-3-butyn-2-ol) [67]. Inhibitors also extend the processing time (pot life) at room temperature. The catalysts are

poisoned by various substances such as compounds of heavy metals (e.g., tin), sulfur compounds (thiols, sulfides, etc.), and nitrogen compounds (amines, isocyanates, etc.).

The molar ratio of the reactants is especially important for optimum curing. A 1.5- to 2-fold molar excess of Si – H groups is generally used to achieve the optimum cross-link density (i.e., by complete reaction of the vinyl groups). It is also possible to produce very soft or gel-like products by incomplete cross-linking.

4.4.3. Condensation Curing

Condensation- curing compounds cure at room temperature and are known as RTV (room temperature vulcanizing) compounds. The elastomeric network is formed by reaction of hydroxy functional polysiloxanes and tri- or tetrafunctional silanes containing hydrolyzable Si – O or Si – N bonds (Table 8). The hydrolyzable groups react with SiOH groups of the polymer or with water to form cross-links.

Table 8. Typical silane cross-linkers

Silane	Cleavage product
$Si(OC_2H_5)_4$, $[SiO(OC_2H_5)_2]_n$, $Si(OC_3H_7)_4$, $CH_3Si(OCH_3)_3$, $CH_3Si(OC_2H_5)_3$	alcohols
$CH_3Si(OCOCH_3)_3$, $C_2H_5Si(OCOCH_3)_3$	acetic acid
$CH_3Si[NH(s{-}C_4H_9)]_3$, $CH_3Si(NHC_6H_{11})_3$	amines
$CH_3Si[O{-}N{=}C(CH_3)C_2H_5]_3$, $Si[O{-}N{=}C(CH_3)C_2H_5]_4$, $CH_2{=}CHSi[O{-}N{=}C(CH_3)C_2H_5]_3$	butanonoxime
$CH_3SiOC_2H_5[N(CH_3)COC_6H_5]_2$	*N*-methylbenzamide, ethanol

Most silane cross-linking agents react spontaneously with SiOH groups or with water. Metal catalysts (Sn or Ti) are generally added to these systems to give complete curing and improve the properties. Alkoxysilanes are an example of cross-linkers that do not cure in the absence of appropriate catalysts.

Condensation curing is used in one- and two-component products, which differ in composition and cure rate.

One- component RTV compounds contain excess cross-linking agent. During compounding the hydroxyl functional polysiloxanes and the cross-linker react to produce polymers with reactive end groups, for example:

In this way, cross-linking of the polymers can be repressed. One- component RTV products are sold in containers sealed against humidity. Curing starts when the compounds are exposed to atmospheric moisture during application. As the remaining free cross-linking agent and the reactive polymer endgroups are hydrolyzed, the resulting SiOH groups react with unhydrolyzed groups to form an elastomer network. The following simplified reaction scheme applies:

One- component RTV compounds are distinguished according to the cure byproducts as acidic, basic or, neutral cure systems (Table 8). Acidic systems contain methyl- or ethyltriacetoxysilane as curing agent and produce acetic acid as byproduct [68]. Basic systems produce amines [69]. Several neutral systems are commercially available. Alkoxy systems use mainly methyltrimethoxysilane [70, 71]. Oxime systems contain methyl(tributanone oximo)silane and give butanone oxime as byproduct [72]. Benzamide systems produce *N*-methylbenzamide as a typical hydrolysis byproduct. The latter remains as a finely divided solid in the cured elastomer [73].

Tetrafunctional alkoxysilanes are generally used as cross-linkers in two- component RTV compounds. They must be used in combination with tin catalysts, whose specific reaction mechanism ensures cross-linking of the OH-functional polysiloxanes, even in the presence of excess cross-linker [74, 75]. The presence of

water is also necessary for curing. Unlike one-component RTV compounds, the process does not involve an intermediate endstopped polysiloxane. The compounds cure uniformly, in contrast to one-component RTV systems, which cure from the surface inward.

4.4.4. Radiation Curing

Radiation-cured products have been unimportant hitherto. This kind of cross-linking is applied principally in processes for which high curing temperatures are not possible [76].

Curing by Ultraviolet Light. Ultraviolet curing has been described for coating temperature-sensitive substrates (paper, films) [77].

Cross-Linking by γ Rays and Electron Beams. Cross-linking under the influence of γ rays or electron beams proceeds via the formation of free radicals [78].

Polydimethylsiloxane rubbers cured with 1 – 5 Mrad of γ rays have similar mechanical properties to peroxide-cured rubbers.

4.4.5. Oxidative Coupling

Polysiloxanes containing mercaptoalkyl groups react rapidly at room temperature in the presence of metal catalysts to form elastomers cross-linked by disulfide bridges [79]. These rubbers lack some of the advantages typical of silicones, such as odorlessness, physiological inertness, and weather resistance.

4.5. Peroxide-Cured High-Temperature Vulcanizing Silicone Rubbers

High-temperature vulcanizing (HTV) silicon rubbers are designed for the processing methods and equipment of the rubber industry.

The viscosity of HTV compounds is in the range of 20 – 100 Mooney units at 25 °C (concentric-disc viscometer DIN 53 523), typical of other rubbers but only at temperatures of 80 – 120 °C.

The base polymers are high-viscosity, vinyl-containing polysiloxanes with only methyl (VMQ), or a mixture of methyl and phenyl (PVMQ) or trifluoropropyl (FVMQ) groups. The vinyl substituents can be present as end groups and along the polymer chain. The vinyl group concentration is commonly between 0.03 and 2.0 mol %.

Production. HTV silicone rubbers can be produced batchwise or continuously from the siloxane polymers, silica fillers, and process aids in conventional rubber mixing equipment.

Suitable mixing equipment includes e.g., twinscrew compounders (2 – 6000 L), internal mixers (Banbury, 1 – 300 L), roll mills (1 – 100 L), twinscrew extruders or Buss co-kneaders (2 – 500 kg/h). The individual machines have different mixing times, but comparable space – time yields [80, 81].

Since hydrophobic silica fillers are not usually employed for mixing, dispersion at temperatures up to ca. 160 °C is often necessary. Unlike the production of temperature-sensitive, high-viscosity organic rubbers, heat – not cooling – must be applied during silicone rubber production.

The rubbers are usually manufactured as pigment- and cross-linker-free compounds. The addition of cross-linking agents (e.g., peroxides), pigments, stabilizers, and optional processing aids is usually carried out by the user on a smaller scale in easily cleaned roll mills. Ready-to-use compounds are marketed on a limited scale by silicone producers.

Processing. HTV silicone rubbers are pasty, translucent or colored materials. In the uncured state at 25 °C they have a lower green strength than other rubbers. To improve the processibility on roll mills (roll workability) and for better demolding, release agents [82, 83], or viscosifying additives such as PTFE powder [84] are sometimes used.

Molding. Peroxide-containing rubbers are prepared for molding as sheets, strips, or granules. Compression-molded articles are produced in steel molds filled by means of a piston or in automatic transfer molding presses and casting machines [60]. Tubes and insulated wires are produced continuously by extrusion. Coatings or coverings are produced on calenders.

Vulcanization. Vulcanization of HTV moldings is carried out in hot compression molds, in steam chambers under pressure, or in unpressurized hot air ovens. Diaroyl peroxides are used for pressureless vulcanization because of their low decomposition temperature (60 – 90 °C) and high cure rate (5 – 20 min at 100 °C).

Curing with diaryl peroxides occurs in a few minutes at 160 – 180 °C. The cure kinetics can be determined with conventional curemeters, which measure an increase in torque as an index of the degree of cross-linking. The time required for a 50 % increase in torque roughly corresponds to the half-life of the peroxide [85]. After curing, volatile siloxanes (0.5 – 1.5 %) and residual peroxide decomposition products must be removed. This is normally accomplished by heat treatment (post-curing) for 2 – 6 h at 200 °C.

High-viscosity silicone rubbers can also be vulcanized by hydrosilylation curing. A precondition is a sufficient concentration of cross-linkable vinyl groups and their appropriate distribution in the polymer. These systems produce high-strength, transparent elastomers free of discoloration. Both compression molding and unpressurized curing can be employed [86, 87].

Cross-linking by condensation reactions is not common for these rubbers due to the long cure times.

Other Forms of Application. Dispersions of HTV rubbers in organic solvents are used to produce coatings such as coated glass fibers and braided cables.

Silicone foam rubber can be produced by adding blowing agents or by hydrosilylation curing in the presence of SiOH groups or water. The latter method involves the evolution of hydrogen (see → Foamed Plastics, Chap. 4.7.).

4.6. Liquid Silicone Rubbers

Liquid silicone rubber (LSR) is a new class of rubber that has grown rapidly in importance since the early 1980s. This rubber was developed specifically for processing on injection molding equipment. LSR compounds exhibit a number of favorable processing properties such as low viscosity and high curing rate and represent an economical alternative to conventional rubber processing due to the lower cost of the finished article.

Liquid silicone rubbers are medium-viscosity materials that can be pumped from the storage vessel to the injection molding machine. Hydrosilylation curing is the exclusive mechanism of vulcanization for this class of rubbers (see Section 4.4.2). Peroxide-cured liquid silicone rubbers are of no commercial importance.

Formulation. Liquid silicone rubber is based on vinyl-containing polydimethylsiloxanes with viscosities about 1000 times lower than for HTV rubber stock. However, the chain length, which is decisive for the development of the elastomer network is only six times lower. To compensate for the relatively short chain length and still maintain an adequate network density, the majority of the polymer must have vinyl end groups. Acceptable reinforcing fillers are pyrogenic or precipitated silicas made hydrophobic by treatment with silylating agents. Filler treatment reduces the mutual interaction of the filler agglomerates to produce compounds that are free flowing despite the high filler content.

Liquid silicone rubbers are formulated as two-component systems to ensure a long shelf life. Only after the two components (A and B) are mixed can the rubber be cured. The A component usually contains the platinum catalyst in addition to the base polymer, while the B component contains the cross-linker (polymethylhydrogensiloxane) and an optional inhibitor in addition to the base polymer.

Liquid silicone rubbers with other base polymers [e.g., methylphenylsiloxane (PVMQ) or methyltrifluoropropylsiloxane (FVMQ)] [88, 89] or other fillers (e.g., carbon black for electrically conductive types) are also available [45].

Processing. Liquid silicone rubber is supplied ready for processing. The two components are conveyed with a metering pump to a mixing head in which an optional dye paste can be separately charged. The material then flows through a static mixer into the automatic injection molding machine (Fig. 9). In a predetermined cycle, the material is injected into the hot mold, held under pressure to cure, then automatically demolded. The molds are mainly of the so-called

cold-runner type, in which the sprue channels are cooled so that no loss of material occurs.

Figure 9. LSR processing

Liquid silicone rubber can be inexpensively processed like thermoplastic elastomers, but has the advantage of being chemically cross-linked. Thus, use temperatures of well above 100 °C are possible.

The cure temperature of LSR is generally between 170 and 230 °C. Cycle times of 15 – 60 s can be achieved, depending upon the wall thickness of the moldings. Many moldings are used as obtained without further treatment. With correct mold design, flash removal is unnecessary. For certain applications, e.g., in the foods industry, post-curing the articles (usually 4 h at 200 °C) is required to remove residual volatiles. Post-curing also removes excess Si–H groups by hydrolysis and partial condensation.

$$\equiv Si-H + H_2O \xrightarrow{Pt} \equiv Si-OH + H_2$$
$$\equiv Si-H + HO-Si\equiv \xrightarrow{Pt} \equiv Si-O-Si\equiv + H_2$$

Post-curing results in new disiloxane bridges and an increase in the network density. After post-curing, further reactions of the Si-H groups are no longer possible. As a consequence, the compression set, an important property for many applications, is reduced to a desirably low level.

Liquid silicone rubber is suitable for producing coatings due to the relatively low viscosity. Special grades with low filler content and, therefore, lower viscosity are available for this application. Unlike many other elastic coating materials, LSR formulations contain no solvent.

4.7. Room Temperature Curing Silicone Rubbers

Silicone RTV (room temperature vulcanizing) systems are classified according to their cure mechanism (hydrosilylation or condensation cure). One- or two-component systems have been developed for different applications. Two-component products, which must be mixed before application, are available with either curing mechanism. One-component RTV compounds are based almost exclusively on a condensation mechanism. These systems cure upon exposure to atmospheric moisture.

Typical RTV silicone products contain polymers with a polydimethylsiloxane backbone [90]. One-component systems, composed of organic polymers with silane end groups [91], are not discussed here.

Water-based silicone sealants are unique one-component systems that consist of an aqueous emulsion of a silicone polymer, fillers, an organotin condensation catalyst, and an anionic surfactant. On application, the water evaporates to give a material that is cross-linked mainly by the filler [92, 93].

4.7.1. Two-Component RTV Systems

Two-component RTV systems are used as pourable potting or casting compounds.

Condensation-Cured Systems.

Composition. The base component contains a hydroxyl-end-capped polydimethylsiloxane (M ca. $10^4 - 10^5$), which may also contain non-reinforcing fillers, unreactive silicone fluid and pigments, as well as small amounts of water and other additives.

The second component (cross-linker), which is sensitive to hydrolysis, contains the cross-linking agent (generally an alkoxysilane) and a catalyst (often the condensation product of an alkoxysilane with a dialkyltin compound).

Processing. The two components are generally used in ratios between 100 : 1 and 10 : 1 (base component to cross-linker). Automatic mixing and dispensing equipment requires a ratio of 10: 1 for reliable operation.

Curing begins shortly after the two components are mixed and is usually complete within several hours to one day at room temperature. Alcohol is generally eliminated during curing and must completely evaporate from the cured elastomer to prevent reversion. The rate of cross-linking and evaporation of the alcohol can be accelerated by raising the temperature.

Hydrosilylation-Cured Systems.

Composition. Hydrosilylation- cured systems consist of two components which are often mixed in the ratio 1: 1. One component contains a polydimethylsiloxane with vinyl end groups, optional fillers, pigments, and the platinum catalyst. The second component contains the cross-linking agent, which is either a polymethylhydrogensiloxane or a copolymer thereof with a polydimethylsiloxane. This component can also contain fillers and a vinyl- containing siloxane.

Processing. Curing begins immediately after mixing the two components. The reaction can be retarded, and hence the pot life increased, by adding low molecular mass cross-linkable components or inhibitors.

4.7.2. One-Component RTV Systems

Uses. One- component RTV silicone compounds are mainly used as sealants in building construction owing to their good stability to weathering [94, 95]. The pastes are formulated to be nonsagging and easily pumpable, so that they can be readily applied. The pastes are packaged in plastic cartridges or, increasingly, tubular plastic bags, which prevent the ingress of atmospheric moisture prior to use.

Numerous industrial applications also exist in which one- component RTV compounds are used as sealants, adhesives, and coatings. The properties of the product are adjusted to suit the application, ranging from easily pourable to highly viscous or rigid compounds, and from low-modulus rubbers to adhesives with high tear strength. Examples include automobile sealants [96], textile coatings, production of insulating glass, contruction adhesives (e.g., for cladding panels), sealing of furnaces, and applications in electrical and electronic engineering [89].

Composition. The base polymers are polydimethylsiloxanes with terminal hydroxyl groups and a viscosity of 1 – 500 Pa · s, preferably 10 – 150 Pa · s. For building construction, where soft vulcanizates are mostly required, nonfunctional polydimethylsiloxane fluids are added as plasticizers. The rigidity is adjusted by adding 7 – 15 wt % pyrogenic silica. Silica of low surface area is preferred (130 – 150 m^2/g). Pigmented compounds often contain inert fillers in addition to silica to lower the cost; ground natural chalk, treated with stearic acid, is used preferentially.

The silane cross-linking agents are used in quantities of 3 – 6 wt %. The amount of cross-linking agent must exceed the quantity required to react with the hydroxyl groups of the raw materials. Neutral systems generally contain an organofunctional silane as coupling agent (e.g., aminopropyltrialkoxysilanes). Dialkyltin carboxylates or chelate complexes of Ti(IV), preferably with acetylacetone or esters of acetylacetic acid, are used as catalysts. Tin compounds are generally employed in amounts of < 0.5 wt %, titanium compounds are used in higher quantities [97].

Building sealants contain inorganic pigments as additional auxiliaries for coloring and biocides to prevent the growth of mold in damp rooms.

Processing. The material is applied by direct injection into the joint from the cartridge or tube by using manual or compressed-air pistols. After a few minutes, an elastic skin forms on the surface under the action of atmospheric moisture. Curing proceeds from the surface to the inside and, with usual joint dimensions, is complete after at most a few days. The rate of curing depends not only on the ambient temperature and humidity, but also on the type of sealant. Silicone sealants generally exhibit high flexibility and good adhesion to a wide range of substrates.

Use of a primer may be necessary for porous substrates and in the case of insufficient adhesion.

Whereas the classical acetate systems dominate in the sanitary sector, neutral systems are being used in increasing amounts, for example, as window sealants. Low-odor, noncorrosive systems can be expected to further increase in importance.

General guidelines for processing of silicones for industrial fabrication cannot be given because of the wide range of applications.

4.8. Paper and Textile Coatings

Silicone elastomers are used in a variety of coating applications. The most important substrates are paper and textiles. The choice of polymer and curing system, the formulation and the coating method depend on the substrate and the desired properties.

4.8.1. Paper Coating

Paper and films are often coated with very thin layers of silicone to make them repellent to adhesive substances.

Paper coating plants operate at high speed (up to 500 m/min), and thus require silicone coating systems that cure rapidly while maintaining a sufficient pot life. Silicone coating materials are two- or multicomponent systems that cure at substrate temperatures of 100 – 130 °C in 5 – 15 s.

The coating mixture must exhibit good wetability, both for the rolls and for the substrate surface, to give pore-free films. Completely cured coatings contain no migrating constituents that can impair the adhesive properties of a subsequently applied adhesive layer. The adhesive is applied directly (on-line process) or in a later manufacturing step. The adhesive forces between the adhesive layer and the silicone coating must remain constant over fairly long periods of storage. This is especially important when controlled-release additives are used to increase adhesion between the silicone and adhesive layers.

At present, the following silicone coating systems are used:

Solvent-Containing Systems.

Condensation systems (I) consist of hydroxyl-end- capped polydimethylsiloxanes and polymethylhydrogensiloxanes as cross-linkers. The cross-linking reaction is catalyzed by organotin compounds:

$$\equiv SiOH + HSi\equiv \xrightarrow{Sn} \equiv SiOSi\equiv + H_2$$

The system is used in dilute form (3 – 5 % in organic solvents). In emulsion form it is diluted to about 10 % with water before use.

Condensation systems (II) contain reactive silanes instead of polymethylhydrogensiloxane. Their curing mechanism is the same as for the moisture- cured RTV compounds (see Section 4.4.3). Systems I and II have been virtually displaced from the market by hydrosilylation-cured systems because of disadvantages such as sensitivity to variations in atmospheric humidity and slow cure even at high curing temperature (20 – 40 s at 120 – 180 °C).

Hydrosilylation- cured systems consist of higher viscosity polydimethylsiloxanes with reactive vinyl groups and polymethylhydrogensiloxanes as cross-linkers. They cure in the presence of platinum complexes (30 – 120 ppm Pt) in 15 – 20 s at 120 – 140 °C (for curing mechanism see Section 4.4.2). They are applied as solutions in organic solvents or as emulsions. With sufficient dilution it is possible to prepare very thin films. The solvent is removed by evaporation during cross-linking and is recovered or burned.

Solvent-Free Systems.

Heat-cured systems are also based on the principle of hydrosilylation curing and differ from the corresponding solvent- containing systems by having shorter- chain vinyl- containing polymethylsiloxanes with a viscosity of 200 – 500 mPa · s. In contrast to solvent- containing systems, the thickness of the solvent-free coating does not change on curing. Therefore, stringent requirements must be met by both the application equipment and the substrates to obtain pore-free films with reproducible coating thicknesses of ca. 1 µm (ca. 1 g/m^2) silicone. Solvent-free systems cure in 5 – 15 s at substrate temperatures of 100 – 120 °C. About 50 % of all sub-

strates are coated with solvent-free systems, and the proportion is increasing.

Photochemically cured systems are not well established in paper coating, in spite of the advantage provided by minimal thermal treatment of the substrates. This method is, however, used for special coating applications [98]. The cross-linking mechanisms are varied, but most systems use UV-absorbing sensitizers to increase the quantum yield.

Radiation-cured systems use high-energy radiation (e.g., electron beams) and do not require sensitizers, but they do require a nitrogen atmosphere to avoid formation of interfering oxygen radicals.

Silicone- coated papers and films are assessed by the following criteria:

Curing of the coating
Abrasion resistance (no rub-off)
Adhesion to the substrate
Porosity of the coating
Magnitude of the release force values
Constancy of the release force values
Residual adhesive forces
Coating strength
Film smoothness

Fields of application for the abhesive coated papers are [100]:

Self-adhesive labels (74 %)
Adhesive tapes (10 %)
Hygienic articles (6 %)
Construction, packaging, decoration, etc. (10 %)

4.8.2. Textile Coating

Textiles can be rendered water-repellent with special silicone fluids that simultaneously provide the fabric with a soft feel. Elastomer systems that are similar in composition to those described for paper coating or for two- component and LSR silicone rubbers are used for waterproof textile coatings that are permeable to water vapor.

4.9. Properties of Silicone Elastomers

The typical properties of silicone polymers are also exhibited by cured silica-reinforced products. They account for the many applications of silicone elastomers. Different combinations of properties can be obtained by choice of polymer, cross-linking system, and compound composition.

Temperature Limits for Silicone Elastomers. Silicone elastomers have the widest operating temperature range of commercially important rubbers. VMQ rubbers exhibit better relaxation properties than other synthetic rubbers, i.e., the compression set has a smaller temperature dependence in the range −40 to 170 °C (Fig. 10) [99].

Figure 10. Compression set versus temperature for some elastomers

Mechanical properties such as tensile strength and tear strength also show only a small temperature dependence between − 40 and 150 °C. The tensile strength of VMQ is strongly enhanced at − 40 °C.

This general behavior must be distinguished from heat stability or changes in the room temperature properties that occur at elevated temperature. The heat stability of elastomers is evaluated by measuring the retained properties after high-temperature ageing (see hot-air resistance).

A phenyl content of 5 – 12 mol % extends the low-temperature flexibility (measured as torsional stiffness, DIN 53 548) from − 45 to − 70 °C and the brittleness point from − 55 to − 105 °C (ASTM D 380) [88].

Phenyl groups improve the resistance to γ rays by a factor of 2 – 5.

Hot-Air and Oxidation Resistance. The high-temperature and oxidation resistance of pure cross-linked polydimethylsiloxane polymers is adequate only up to 200 °C. Above this temperature, oxidation reactions at the alkylene cross-links and methyl groups cause embrittlement. Oxidation can be inhibited by using hot-air stabilizers (see Section 4.2). Further improvement is achieved by limiting the content of acidic Si – OH groups in the silica filler.

Since even low contents of acidic and alkaline impurities lead to depolymerization (reversion) of the network, the polymers must be thoroughly neutralized. Stabilizers that neutralize acidic decomposition products from cross-linking agents, for example, are added optionally. Elastomers stabilized in this way withstand exposure to hot air at 300 °C for up to 21 d. After an induction period, embrittlement increases logarithmically with time.

Steam, Chemicals and Oil. Despite the sensitivity of the Si – O bond to acids, bases, and to water at elevated temperature, the stability of silicone elastomers can be significantly improved by increasing the cross-linking density and by using additives [52, 101].

Patents describe the use of combinations of CaO and silanes containing methacrylic groups to improve the oil resistance [102]. Additives such as mica or diatomaceous earth have a similar effect [103, 104]. The swelling rate can be appreciably reduced by using fairly large amounts of vinyl resins [105]. Stabilized VMQ rubbers withstand immersion in ASTM 2 oil for up to 2000 h and in ASTM 3 oil for up to 500 h.

Swelling rate depends on the solubility parameters χ of the siloxane and the contact medium. Similar χ values result in higher swelling rate [106]. Additional degradation by acids or bases occurs in technical applications. Silicone elastomers with enhanced oil resistance usually have a high filler content and thus a reduced siloxane and stabilizer content.

A large decrease in the swelling rate can be achieved by changing the solubility parameter of the polymer (e.g., by using fluoroalkyl-modified siloxanes) [89].

Another method to improve the oil resistance is to blend silicone elastomers with solvent-resistant rubbers such as acrylonitrile or fluorinated rubbers [107–110]. These blends can exhibit improved low-temperature and swelling behavior. Interest in blends has increased with the introduction of new peroxide- curable fluorinated rubbers [107, 111].

Reversion – Compression Set. Reversion and increased compression set are often induced by the action of water vapor and acid or base. The resulting breakdown of the polymer network can be counteracted by polymer neutralization and by using the maximum possible cross-link density. Compression set can also be reduced by using neutralizing additives or by the addition of methylhydrogensiloxanes [52, 101, 112].

High-Strength Formulations. The room-temperature tensile strength of silicone elastomers of 6 – 12 MPa is lower than that of other common elastomers (10 – 30 MPa). The tear strength is also only moderate (10 – 30 N/mm, compared to 20 – 80 N/mm), according to ASTM 624 D die B. Much effort has been targeted at improving the tear strength of silicone elastomers [113–119]. The tear propagation strength can be increased to 40 – 55 N/mm by optimizing the polymer structure.

Adhesion. Silicone elastomers are often used in composite structures with other materials. Here, adhesion of the elastomer to the other material is particularly important.

Owing to their cross-linking mechanism, condensation cross-linking systems show good adhesion to surfaces with hydroxyl groups. The hydroxyl groups on the surface react with the SiOH or SiOR groups of the polymer. Good adhesion is observed to glass and to metals with oxide or hydrated surfaces, such as aluminum and iron. Condensation systems with and without solvent are also used as coupling agents or adhesives for other silicone elastomers.

For good adhesion peroxide- and hydrosilylation- cured rubbers frequently require primers that are applied as coupling agents to the surface of the material. With the proper choice of primer, good adhesion can even be obtained on many plastic surfaces [120–123].

Electrical Properties. Siloxanes and their mixtures with pyrogenic silica have a very good electrical insulating capacity. The electrical properties are temperature dependent and are strongly affected by exposure to water. Accordingly, the resistivity of $10^{16}\,\Omega\cdot$cm under dry conditions at 20 °C decreases to $10^{12}\,\Omega\cdot$cm at 160 °C and 50 % R.H. [32].

The use of precipitated instead of pyrogenic silica leads to a decrease in resistivity and, because of the higher water content of the filler, to an increase in dielectric constant. The addition of carbon blacks [124], sometimes in combination with conducting powders or fibers [125, 126], can lower the resistivity to $3\,\Omega\cdot$cm (ISO 1853).

Thermal Properties. The thermal conductivity of silicone elastomers can be increased by large amounts of inert fillers such as quartz, AlN, Al_2O_3, Si_3N_4, or MgO [41, 43, 127, 128].

Burning Properties. The heat evolution from siloxanes on burning is lower and accordingly more favorable than that of pure organic elastomers [129, 130]. A residual electrical insulating capacity is maintained, even after burning, as a result of the remaining silica framework.

Flame retardants can effectively suppress the further combustion of silicones after ignition. In this way, transparent or colored elastomers can be produced that pass flammability tests such as UL 94 V1 or V0 [59]. The combustion gases formed are less toxic than those from halogen- or nitrogen-containing elastomers [129–132].

Gas Permeability. Silicone elastomers dissolve many gases well and are highly permeable. The high gas permeability [133] is somewhat selective and depends on the substituents [134–137]. Silicone elastomers are therefore suitable for the production of gas-separation membranes [138] and for oxygen-permeable contact lenses or dressings for wounds [139–141].

Transparency. The extremely small primary particles of well-dispersed high surface area silica fillers in silicone elastomers cause only minor light scattering. With a UV transmission (DIN 5033) of up to 90 %, they are almost transparent [46] and are therefore used as contact and other lenses [140]. This high transparency is achieved by special hydrophobic treatment of the filler with strong silylating agents [142]. A further enhancement of the transparency is possible by incorporating phenyl groups into the polymer, which shifts the refractive index n_D^{20} from 1.39 to 1.43 – 1.47 [143–145]. Recently, more rigid silicone – acrylate copolymers have been preferred for contact lenses [146].

Physiological Behavior. Because silicone elastomers exhibit low surface tension and are abhesive, interactions with surfaces of living tissues, cells, or blood platelets are very weak [146–148]. Therefore, filler-free elastomers, in particular, are suitable for implant applications. Numerous surgical and medical applications exist. Another advantage of silicone elastomers is that they can be sterilized in steam above 100 °C.

4.10. Applications

The typical properties of silicone elastomers lead to their application in areas involving:

1) Electrical insulation or conduction
2) High and/or low temperatures
3) Weather and UV exposure
4) Oil and hot-air contact
5) Dynamic stress
6) Flame resistance, arcing resistance
7) Gas permeability
8) Contact with foods
9) Contact with living tissue
10) Abhesive surfaces
11) Transparent articles of high optical quality

Examples of uses of silicone elastomers are listed below:

Electrical
wire insulation
cable sheaths
power cable endcaps

Electronic
anode caps
coatings
encapsulation
fiber-optic coatings

Household
pot seals
coffeemaker tubes and seals

baby bottle nipples
oven gaskets
anti-stick papers

Automobile
gaskets
cable guides and connectors
headlight seals
shaft seals
O-rings
cooling and turbo hoses
oil pan gaskets
spark plug boots
air bags
ignition cables
fuel line diaphragmas and seals
exhaust pipe hangers
axle boots

Airplane
headlight seals
window seals
interior joints and floors
vibrational damping

Office machines
keyboard pads
copier rolls

Medicine and dentistry
tooth impression compounds
implants
pumps
heart valve seals
catheters
membranes
lenses
controlled drug release

Paper and Textiles
coatings
conveyor belts

General
casting forms
membranes
impression molding compounds
anti-stick bladders
divers' masks
protective masks

5. Silicone Resins

5.1. Structure and General Properties

Alongside fluids and elastomers, silicone resins are the third important class of materials produced by hydrolysis or alcoholysis of organochlorosilanes [149, 150].

Whereas silicone fluids and elastomers are based on linear polymers, silicone resins are highly branched, containing significant quantities of trifunctional (T) or tetrafunctional (Q) units.

By combination of T and Q units with difunctional (D) and monofunctional (M) units, a large number of different resin structures can be formed, in which the proportion of the various silicone units can vary over a wide range.

The properties of silicone resins are strongly influenced by the organic groups bonded to silicon. The most frequently used monomers are methyltrichlorosilane, phenyltrichlorosilane, dimethyldichlorosilane, and diphenyldichlorosilane. Pure T resins are relatively brittle and exhibit little thermoplasticity. The hardness can be decreased by adding D and M units. An increased dimethylsiloxane content, in particular, leads to products of increased elasticity and adhesion, but also increased tendency to yellow at high temperature. With increasing temperature, the hardness of the resins decreases. This effect is stronger when diphenyldichlorosilane is used. The introduction of phenyl groups has a plasticizing effect. Simultaneously, the resistance of the polyorganosiloxanes to heat and weathering is increased, and their compatibility with organic polymers, their pigmentability, and their yellowing resistance are improved. Products with increased alkali resistance required for masonry protection are obtained by using special silicone resins.

In addition to pure silicone resins, combination resins also play an important role [151, 152].

Combination resins are produced by cocondensation of silicone resins having hydroxyl or alkoxy groups with functionalized organic resins such as polyester, alkyd, acrylic, or epoxy resins. Compatibility of the resins is improved by using methylphenylsilicones.

5.2. Production

Silicone resins and their precursors are generally produced from mixtures of the corresponding organochlorosilanes by hydrolysis or alcoholysis. From a given mixture, completely different cross-linked structures with markedly different properties can be obtained, depending on process conditions. The simplest case – addition of the silane mixture to the hydrolysis medium – is known as direct hydrolysis. Since the chlorosilanes are immiscible with water and the individual silanes hydrolyze at different rates, this can lead to nonuniform products and, in the worst case, gelation.

In reverse hydrolysis, in which the hydrolyzing medium (usually an alcohol – water mixture) is added to the silane mixture, a more uniform cohydrolysis is achieved and gelling is largely avoided. However, low-boiling starting materials may be lost, together with escaping hydrogen chloride.

Both processes can be improved by adding solvents. Solvents immiscible with water, such as toluene, xylene, or cyclohexane, lower the silane concentration and the concentration of reactive hydrolysis condensate at the interface, and repress the influence of hydrochloric acid, which promotes condensation. The process can be further improved by using solvents miscible with both water and silane (two-phase solvents), such as acetone. A short- chain alcohol such as butanol is often used to lower the reactivity of the system by forming alkoxysilanes. A drawback of the two-phase solvent is the relatively high concentration of organic substances in the wastewater.

Silicone resins are commonly bodied following hydrolysis by heating in the presence of mild condensation catalysts. This step is used to control the viscosity and cure properties of the resin. In this reaction the functional groups condense according to

$$\equiv\mathrm{Si}-\mathrm{OH}+\mathrm{HO}-\mathrm{Si}\equiv \longrightarrow \equiv\mathrm{Si}-\mathrm{O}-\mathrm{Si}\equiv+\mathrm{H_2O}$$

or

$$\equiv\mathrm{Si}-\mathrm{OH}+\mathrm{RO}-\mathrm{Si}\equiv \longrightarrow \equiv\mathrm{Si}-\mathrm{O}-\mathrm{Si}\equiv+\mathrm{ROH}$$

The condensation process is frequently accompanied by viscosity monitoring and terminated by cooling, neutralization, or dilution when the desired properties are attained.

The nature and concentration of the remaining reactive groups and the molecular mass distribution determine many of the further processing and product properties.

Combination resins are formed by reaction of siloxane precursors with hydroxy-functional organic esters (e.g., polyesters), alkyd resins, acrylates, or epoxy resins

$$\equiv\mathrm{Si}-\mathrm{OH}+\mathrm{HO}-\mathrm{C}\equiv \longrightarrow \equiv\mathrm{Si}-\mathrm{O}-\mathrm{C}\equiv+\mathrm{H_2O}$$

and

$$\equiv\mathrm{Si}-\mathrm{OH}+\mathrm{RO}-\mathrm{C}\equiv \longrightarrow \equiv\mathrm{Si}-\mathrm{O}-\mathrm{C}\equiv+\mathrm{ROH}$$

The hydrolysis of chlorosilanes with subsequent condensation is irreversible. Alcoholysis products can be improved by an optional acid- or base- catalyzed equilibration stage. Although silicone resins can be produced continuously [145, 153–155], many products with relatively low demand are produced in batch processes.

5.3. Curing

Silicone resins can be cured by the same reaction mechanisms as silicone elastomers. The most common method of curing silicone resins is metal- catalyzed condensation, preferably with complexes of tin or titanium. Resins containing vinyl groups can be cross-linked by peroxides. The simultaneous presence of silicon-bonded hydrogen and of vinyl groups enables curing by noble-metal catalyzed hydrosilylation (see Section 4.2). Radiation-induced curing reactions are also possible. Above 150 °C in air, oxidative degradation occurs and is accompanied by curing, for example,

$$\equiv\mathrm{Si}-\mathrm{CH_3}+\mathrm{CH_3}-\mathrm{Si}\equiv \xrightarrow{\Delta,\ \mathrm{O_2},\ \mathrm{cat.}} \equiv\mathrm{Si}-\mathrm{O}-\mathrm{Si}\equiv$$

This curing mechanism is exploited in the use of silicone resins as binders in the paint industry, for example, in high-temperature anticorrosion coatings, release coatings, or decorative coatings for kitchenware [156].

5.4. Properties

The characteristic properties of silicone resins are their high resistance to temperature and weathering. The weather resistance includes UV and oxidative stability, as well as stability to aqueous acids, fats, and oils. The behavior toward fats and oils also enables the use of silicone resins as release coatings. Silicone resins are water repellent and, like all silicone polymers, permeable to gases. They also show good wetting properties on many inorganic and organic substrates.

After curing, silicone resins exhibit good adhesion to most surfaces due to chemical or physical bonding to the surface. They are electrically nonconductive, and their electrical and mechanical properties show little dependence on temperature. The susceptibility to oxidation, especially of the pure methylsilicone resins, is low. Decorative and gloss-retaining effects, as well as elasticity and pigment compatibility, increase with increasing phenyl content, but the hardness decreases simultaneously. By varying the organic substituents of the resin, desirable resin properties can be adjusted selectively. Provided certain preconditions are met, silicone resins are physiologically inert [157, 158].

5.5. Applications

Silicone resins have a wide range of applications, the most important being paint binders and masonry protection. In the electrical industry, silicone resins are used as binders for compression molding compounds and laminates (glass fabric, mica), as well as for impregnating resins and insulating varnishes. Electronic chips and other components are protected from moisture, dust, and chemicals by silicone-resin-based coatings. Unlike conventional coating materials such as phenolic or epoxy resins, silicones exhibit both water repellency and good heat resistance. For high-temperature applications [155], methylsilicone resins are generally used. Silicone-resin-bonded mica laminates are widely used as supporting elements for resistance heaters. In anticorrosion paints, the resins are pigmented with aluminum, zinc dust, or micaceous iron oxide. In decorative coatings, where paint properties such as pigmentability, elasticity, adhesion, and gloss are the overriding concern, methylphenylsilicone resins are generally used. The required temperature resistance of between 250 °C (household appliances) and 400 °C (ovens) can be met. Silicone resins are also used as release coatings (e.g., for baking pans). Silicone resins can be used to protect buildings against graffiti.

Heat-resistant stoving paints, such as those used for the decorative coating of household appliances or for coating metal cladding panels by the coil-coating process [159], frequently consist of silicone–polyester combination resins. The silicone resin gives increased resistance to weathering and chalking, especially in the coil-coating field.

Special silicone resins are used as paint additives to improve specific paint properties [160]. Silicone resins are used in masonry protection. Porous inorganic building materials are rendered water repellent by impregnation with silicone resin. This also increases the resistance to chemicals while maintaining gas and water vapor permeability.

The effectiveness of silicone resins in the protection of building materials depends on the depth of penetration into the substrate. To meet the demand for solvent-free products, silicone emulsions and microemulsions are available [161, 162]. Microemulsions contain up to 20 wt % solids and have particle sizes of 10–80 nm; they have good penetrating power for most building materials. Silicone resin microemulsions are diluted with water before use.

Other applications of silicone resins are as scratchproof coatings for glass and plastics and in polishes. QM resins are commonly used for coatings and in elastomer reinforcement.

6. Block and Graft Copolymers

Polysiloxanes (A) and organic polymers (B) can be chemically linked to give block or graft copolymers. Block copolymers with linear AB, ABA, or $(AB)_n$ structures can be prepared selectively. Grafting reactions lead to statistically distributed branches on the base polymer.

6.1. Polysiloxane – Polyether Copolymers

The most important siloxane-containing copolymers are the polysiloxane – polyether copolymers [163–170]. Both linear and branched block copolymer structures are possible. Branched copolymers consisting of a polysiloxane core and linear polyether side chains are of particular importance. The polyether segments can be polyoxyethylene, polyoxypropylene, or poly(oxyethylene – oxypropylene) units (see → Polyoxyalkylenes). The copolymers can have Si–O–C as well as Si–C linkages between the polysiloxane and polyether segments. Copolymers with Si – O – C linkages are produced by reaction of siloxanes having reactive end groups with polyether alcohols, for example,

$$\equiv\mathrm{Si{-}X} + \mathrm{HO(CH_2CH_2O)}_n\mathrm{R} \longrightarrow \equiv\mathrm{Si{-}O{-}(CH_2CH_2O)}_n\mathrm{R} + \mathrm{HX}$$

X = Cl, OR, OAc, NR_2, H

The Si – C linked copolymers are generally produced by platinum-catalyzed hydrosilylation of polyethers having unsaturated end groups with SiH-containing siloxanes

$$\equiv\mathrm{SiH} + \mathrm{CH_2{=}CHCH_2O(CH_2CH_2O)}_n\mathrm{R} \longrightarrow \equiv\mathrm{SiCH_2CH_2CH_2O(CH_2CH_2O)}_n\mathrm{R}$$

R = H, alkyl

Polysiloxane – polyether copolymers have surfactant properties. The surface tension of aqueous solutions of these copolymers can be as low as 20 mN/m (see Table 9) [169], which is 5 – 8 mN/m lower than comparable organic surfactants. The chain length and structure (linear or branched) of the siloxane component have a strong influence on surface tension, whereas the chain length of the polyether segment has only a minor effect.

Unlike most organic surfactants, polysiloxane – polyether copolymers can also lower the surface tension of organic liquids [169, 170].

Polysiloxane – polyether copolymers are used in large quantities as foam stabilizers in the production of polyurethane foams [164–170]. In this application, the role of the copolymer includes not only lowering the surface energy to promote nucleation, buildup, and stabilization of the foam cells, but also emulsification of the polymer and blowing agent. Branched copolymers with poly(oxyethylene – oxypropylene) segments have a particularly good combination of these properties. The foam-stabilizing action of these copolymers can also be applied to phenolic resin foams [171].

Table 9. Surface tension of aqueous solutions of polysiloxane – polyether copolymers

Copolymer*	Surface tension, mN/m
$[MD]_2D'(EO)_{11.8}Me$	20.0
$MD_3M'(EO)_{11.8}Me$	20.2
$D_3D'(EO)_{8.0}Me$	20.5
$MM'(EO)_{4.8}Me$	21.4
$D_4[M'(EO)_{8.5}Me]_2$	23.4
$[D'(EO)_4Me]_4$	26.3
Water alone	72.0

6.2. Other Block Copolymers

Siloxane-containing block copolymers are known with a variety of organic building blocks, such as polycarbonate [172–175], polyurea [176], polyimide [177], polyester [178], polyurethane [179, 180], polyarylether [181, 182], polylactam [183], polystyrene [184–191], polybutadiene [192], and carbodiimide [193].

Suitable synthetic routes involve terminally reactive polysiloxanes, which either are present during polymerization of the organic monomer [172]:

or react with stoichiometric amounts of functional organic polymer blocks [178]:

Block copolymers can be prepared from some organic monomers by means of living anionic polymerization (e.g., styrene, α-methylstyrene, and butadiene). In this process, the organic monomer is polymerized anionically; then the still-active ends of the polymer are used to polymerize hexamethylcyclotrisiloxane under nonequilibrating conditions [163, 184–189]. By varying this process, AB, ABA, or $(AB)_n$ block copolymers can be produced selectively. Polysiloxanes with bis(silylpinacolate) groups initiate radical polymerization of certain organic monomers to give block copolymers [190, 191].

Silarylenesiloxane – siloxane block copolymers with different silylarylene groups and various organic substituents on the siloxane segments are known:

The silarylene segments readily form crystalline phases, which give the copolymers elastomeric properties. Copolymers have been synthesized with good mechanical properties, stability to oxidation at elevated temperature, and good chemical resistance [194–197].

The polysiloxane and polyorgano segments of block copolymers are usually incompatible. Most block copolymers therefore have a detectable two-phase morphology. For example, in dynamic – mechanical studies on polysiloxane – polystyrene $(AB)_n$ copolymers, two glass transition temperatures were detected, one at $-110\,°C$ for the polysiloxane phase and a second at $+90\,°C$ for the polystyrene phase [189].

Block copolymers with thermoplastic segments can behave as thermoplastic elastomers (TPE). The thermoplastic phase causes physical cross-linking of the elastic polysiloxane segments [198, 199]. The morphology and mechanical properties of the TPEs depend critically on the content of thermoplastic and the chain length of the siloxane segments. The mechanical properties obtained are in some cases superior to those of conventional filled silicone elastomers.

6.3. Graft Copolymers

The radical copolymerization of polysiloxanes with various vinyl monomers (e.g., styrene, acrylates, or vinyl acetate) leads to multiphase graft copolymers [200–206]. Polysiloxanes with reactive functional groups on the siloxane chain, such as mercaptopropyl and vinyl groups, can also be grafted onto organic polymers with reactive groups.

Graft copolymers can stabilize dispersions of organic thermoplastics in polysiloxanes, which can then behave as reinforced elastomers. If hydroxyl-end- capped polysiloxanes are grafted

with thermoplastics, copolymers are obtained that can be formulated with condensation cross-linking agents to give one- or two-component RTV systems. These elastomers can have good mechanical properties and have various applications as embedding materials and coating compounds [207, 208].

6.4. Applications of Block and Graft Copolymers

Polysiloxane – polyether copolymers are important surfactants that are used not only as foam stabilizers but also as leveling agents in paints, release aids, textile auxiliaries, and additives for cosmetics and polishing agents. Siloxane-containing copolymers have various applications as modifiers for thermoplastics. They improve the impact resistance [209] and surface properties [210], and act as flame retardants [211]. The stability of polysiloxanes toward oxidation at elevated temperature and the good low-temperature flexibility are advantageous in these applications. Because of the high oxygen permeability of polysiloxane-containing copolymers, they can be used for making contact lenses. The high gas permeability of polysiloxanes leads to applications as gas-separation membranes. Their use in numerous biomedical applications such as dialysis membranes is described in [141].

7. Analysis

The wide range of chemical and physical methods available for analysis of silicones is outlined below. A comprehensive updated description of these chemical analyses, spectroscopic, chromatographic, X-ray, and microscopic methods, together with ca. 1400 references to the original literature, can be found in a standard work on silicone analysis [212].

Silicon Content. In many cases, determination of the silicon content is sufficient to characterize the silicone content of the substance to be analyzed. Gravimetric, spectrophotometric, and atomic spectroscopic methods are available. To an increasing extent, however, species-specific analysis is required. This is performed by gas chromatography or by combining separation methods with spectroscopic determination.

Determination of Total Silicon Content by Gravimetric and Spectrophotometric Methods. The standard gravimetric method for determining total silicon involves fusing the sample with Na_2O_2 in a nickel bomb. The fusion cake is treated with water, and silicon is separated as SiO_2 by repeated fuming with hydrochloric acid. The final determination is performed by differential weighing before and after removal of the silicon as SiF_4 by fuming with $HF-H_2SO_4$ [213].

Another established gravimetric method is to convert the silicon in the fusion solution to molybdosilicate, to precipitate the latter with organic nitrogen compounds (e.g., pyridine hydrochloride), and to heat the precipitate to give the stoichiometrically defined mixed oxide $SiO_2 \cdot 12MoO_3$. Because of the favorable weight increase, this method is particularly suitable for determining low silicon contents [214].

Very low silicon contents are determined spectrophotometrically after conversion to molybdosilicate. Both the yellow coloration at 390 nm and the blue coloration at 815 nm obtained after reduction with ascorbic acid or 1-amino-2-naphthol-4-sulfonic acid are suitable for this purpose [215].

Determination of Total Silicon Content by Atomic Spectroscopic Methods. Organosilicon compounds can be determined in organic solvents by atomic absorption spectrometry in a nitrous oxide – acetylene flame or by atomic emission spectrometry in an argon plasma. The most suitable solvents are methyl isobutyl ketone, toluene, and xylene. These methods are readily applicable only to nonvolatile organosilicon compounds. Volatile compounds give variable signals, which causes problems in calibration.

Determination of Functional Groups.

Si – Cl. The Si – Cl groups are hydrolyzed to Cl^-, which is titrated argentometrically. Potentiometric end-point detection is recommended, with a chloride-selective or silver electrode as indicator electrode [216]. With low chloride concentrations, the titration should be performed in acetic acid – water mixtures (ca. 4: 1).

Si – H. The Si – H bond is reacted with excess oxidizing agent (e.g., $HgCl_2$ [217], bromine

Table 10. Important IR bands of silicones

Group	Wave number, cm^{-1}, and intensity ∗ of band		
≡SiOH	3685	(m)	free silanol groups
	3200 – 3500	(s)	associated silanol groups
≡SiH	2100 – 2300	(s)	
$\equiv SiCH_3$	1250 – 1280	(s)	
	860 – 750	(s)	
$\equiv SiC_6H_5$	1120	(s)	
	1590	(m)	
≡Si−O−Si≡	1130 – 1000	(s)	broad, possibly several maxima
$\equiv Si-CH{=}CH_2$	1400	(s)	

∗ s = strong; m = medium.

[218], or bromosuccinimide [219]), and the excess oxidizing agent is determined iodometrically. The solvents used are di-*sec*-butyl ether, carbon tetrachloride, acetic acid, or mixtures thereof. The Si – H bond can also be determined gas volumetrically after decomposition by alkali. *n*-Butanol is suitable as solvent and sodium butoxide as decomposition reagent.

Si – OH is determined gas volumetrically, the method being based on the formation of methane in the Zerewitinoff reaction with methylmagnesium chloride or on the formation of hydrogen in the reaction with lithium aluminum hydride [216].

Si – vinyl is determined gas chromatographically as ethylene after alkaline cleavage of the Si – C bond [220]. Iodometric titration of the Si – vinyl bond is possible after reaction with excess bromine solution in a 1: 1 acetic acid – carbon tetrachloride mixture. In the case of polymers, $HgCl_2$ may be required as catalyst. The method is not applicable in the presence of compounds containing other unsaturated groups or SiH groups [221].

Infrared Spectroscopy. The effectiveness of IR spectroscopy in qualitative and quantitative analysis has been increased markedly by the use of computer-interfaced FT-IR spectrometers. It is a rapid and easily used method for qualitative characterization, even of mixtures. The very specific IR bands of silicones allow their detection in a wide variety of preparations. Infrared spectroscopy thus complements other chemical and physical methods. Aside from the usual absorption techniques, ATR (attenuated total reflection) and FMIR (frustrated multiple internal reflection) are important for the investigation of cross-linked, insoluble silicones (rubbers, coatings).

Quantitative analysis can also be conveniently performed by using the specific IR bands of silicones. The intense $Si-CH_3$ band at 1258 cm^{-1} is suitable for determination of the silicone content in the principal and trace ranges. The Si – OH content is determined from the intensity of the free SiOH band at 3685 cm^{-1} in dilute CCl_4 solutions by differential spectroscopy against an SiOH-free siloxane [222]. Another method uses the Si – OD bands after deuteration [223].

Table 10 lists some particularly prominent IR bands of silicones. Further details can be found in [212].

Nuclear Magnetic Resonance Spectroscopy. Of the three possible methods, ^{1}H, ^{13}C, and ^{29}Si NMR spectroscopy, ^{1}H and ^{29}Si are preferred for the analysis of silicone polymers. The recording of a ^{1}H NMR spectrum requires 3 – 10 min, and that of a ^{29}Si NMR spectrum 3 – 10 h. The ^{13}C spectrum usually yields no information beyond that of ^{1}H NMR, while requiring a longer acquisition time.

^{1}H NMR. The typical chemical shifts of substituents bonded to silicon permit both qualitative identification and quantitative determination of the structural groups in silicone polymers. Table 11 lists typical shift values.

Use of *^{29}Si NMR* spectroscopy provides detailed information on the silicone backbone (see also Table 12). It enables:

1) Quantification of the proportions of M, D, T, and Q units in the polymer

2) Qualitative and quantitative analysis of neighboring groups
3) Determination of the proportion of functional groups and end groups in the polymer
4) Conclusions about asymmetry, tacticity, ring conformations, etc.

Table 11. Typical ^{1}H NMR chemical shifts of silicone polymers (relative to $SiMe_4$, solvent $CDCl_3$)

Group	Chemical shift, ppm
$\equiv Si-CH_3$	0.0
$\equiv Si-CH_2-$	0.5
$\equiv Si-OCH_3$	3.5
$\equiv Si-H$	4.7
$\equiv Si-CH{=}CH_2$	5.8–6.2
$\equiv Si-C_6H_5$	7.3 (intensity 3); 7.6 (intensity 2)

Table 12. Typical ^{29}Si NMR shifts in silicone polymers (relative to $SiMe_4$, solvent $CDCl_3$)

Group		Chemical shift ∗, ppm
$-Si(-CH_3)_3$	(M)	+ 8
$-Si(-CH_3)_2(-H)$		− 5
$-Si(-CH_3)_2(-CH{=}CH_2)$		− 5
$-Si(-CH_3)_2(-OH)$		− 10
$-Si(-CH_3)_2(-OCH_3)$		− 12
$=Si(-CH_3)_2$	(D)	− 20
$=Si(-CH_3)(-H)$		− 35
$=Si(-C_6H_5)_2$		− 45
$=Si(-CH_3)(-OCH_3)$		− 56
$\equiv Si(-CH_3)$	(T)	− 65
$\equiv Si(-C_6H_5)$		− 78
$=Si=$	(Q)	−100

∗ Typical values when all other substituents of Si are attached via $-O-Si$.

8. Toxicology

The toxicology of silicones, especially polydimethylsiloxanes, has been thoroughly studied because they are used in medicine and medical technology, as well as in cosmetics.

The inertness of silicones toward warm-blooded animals has been demonstrated in a number of tests [224]. A single large oral dose of PDMS has only a laxative effect in test animals. The LD_{50} in rats is > 50 g/kg. After single dermal or inhalative administration, no effects on animals were observed. Skin contact with PDMS does not cause irritation. After contact with the eyes, temporary irritation of the conjunctiva and possible lachrymation can occur.

Studies of chronic oral administration of PDMS to various animals did not reveal harmful effects. Oral intake of PDMS by humans (e.g., in the treatment of flatulence) causes no undesirable side effects. Regular dermal application in humans (e.g., as a skin cream) is also tolerated without problems, and sensitization has not been observed. The inhalation of PDMS-containing aerosol for 90 d by experimental animals had no effect. However, injection into the trachea led to pathological changes in the lungs. In animals, subcutaneously injected PDMS remains at the place of injection in subcutaneous cysts. Acute and chronic studies show that polymeric siloxanes cannot penetrate cells, and that cleavage of the Si–C or Si–O bonds does not occur in the body.

Various tests have given no indication of mutagenicity.

Studies on the carcinogenic effect of PDMS after oral administration in rats and mice showed no positive findings.

Repeated subcutaneous injection of PDMS in animals led to increased tumor formation at the site of injection. The tumors were not attributed to the chemical activity of PDMS but to the physical properties of the substance.

Implantation of weakly cross-linked silicone gels under the skin of human beings is currently a subject of controversy. Cases are reported in which health problems have arisen.

A panel of experts of the FAO and WHO considers the daily intake by human beings of 1.5 mg of PDMS per kilogram of body weight in the form of food additives to be unobjectionable. The molecular mass of the PDMS used must exceed 200.

In Germany, silicones are permitted in the production of consumer articles for food contact, provided Recommendation XV of the BGA is followed. Similar EC regulations are currently being prepared on the use of silicones in the production of consumer articles that come in contact with foods.

In the case of organofunctional polysiloxanes, toxic effects cannot be excluded, because of the reactivity of the organofunctional groups. Polysiloxanes containing trifluoropropyl groups form toxic decomposition products when heated above 280 °C [225].

9. Environmental Aspects

Introduction into the Enviroment, Behavior in the Environment. Owing to their diverse applications, silicones, especially silicone fluids, enter the environment from diffuse sources (e.g., in wastewater).

Polydimethylsiloxanes are nonbiodegradable [226]. However, PDMS in wastewater is largely eliminated in treatment plants by absorption on sewage sludge [227]. Sewage sludge is burned or applied, either as compost or directly, to areas under agricultural use. Traces of siloxanes have been detected in soil [228]. As a result of dumping sewage sludge at sea, siloxanes enter marine sediments [229].

Siloxanes in natural bodies of water are adsorbed on suspended particles and deposited in the sediment [230]. Traces of siloxanes have been found in sediment [228, 229, 231].

Abiotic degradation paths of siloxanes have been demonstrated in soil and aqueous media. Siloxanes adsorbed on soil are degraded by the catalytic effect of certain clay minerals [232]. Siloxanes dissolved in water (e.g., siloxanols) can be degraded to silicates by indirect photochemical reaction [233, 234].

Oligomeric siloxanes can enter the atmosphere due to their volatility. In the atmosphere these compounds are degraded with a half-life of a few days by photochemically induced oxidation [235–237].

After use, solid silicones (e.g., silicone rubber, resins) are disposed of as waste or incinerated. On complete combustion, SiO_2, CO_2, and H_2O are formed. Solid SiO_2 is removed from the flue gas by dedusting. It is not known whether silicones are degraded (biotic or abiotic) in landfill sites.

Behavior toward Organisms in the Environment. The solubility of PDMS in water is very low. Polydimethylsiloxanes dissolved in water have no harmful effects on aquatic organisms (plankton, crustacea, mussels, fish) [238]. Silicone fluid administered with food exhibits no effect on fish [239]. The symbiosis of microorganisms (bacteria, algae, protozoa) is also not disturbed by siloxanes dissolved in water [230].

Polydimethylsiloxanes in the form of an emulsion enter surface water at higher concentrations than the solubility of pure PDMS. In tests, emulsion concentrations up to 10 000 ppm PDMS in water exhibited toxic effects on fish, but these are attributed to the emulsifier [226, 240, 241].

Sediment enriched in PDMS (up to 1000 mg/kg) has no effect on organisms living in the sediment [242].

Polymeric siloxanes of high molecular mass do not accumulate in aquatic organisms, even when they are fed PDMS- containing nutrients [241, 243].

Oligomeric siloxanes of molecular mass up to ca. 1000 are absorbed by tissue and accumulated. After transfer of the fish to uncontaminated water, absorbed siloxanes were rapidly eliminated from the tissue [243–246].

Summary. Liquid and volatile siloxanes enter the environment as a result of use. Soil (sewage sludge) and sediment are sinks, and siloxanes are found in trace amounts in these environmental compartments. Siloxanes have no marked harmful effects on organisms in the environment. Therefore they are assumed not to represent an environmental hazard.

10. Economic Aspects

Silicones have been produced industrially since the early 1940s. With the industrial-scale realization of methylchlorosilane synthesis (Rochow direct synthesis), the basis was created for a rapid increase in sales worldwide, beginning in the United States. Given the considerable innovation potential of this product group, this trend is likely to continue.

One reason for this development is the diverse molecular structure of siloxanes, and the intimate interrelationship of structure and properties not obtainable for any other class of polymers. Thousands of industrial products have been developed, ranging from fluids to rubbers and resins. Silicones as such or in various formulations, are used in most industries and spheres of life.

Worldwide silicone production can be estimated from the production of organochlorosilane precursors. From 1 kg of dimethyldichlorosilane, about 0.5 kg of dimethylsiloxane is obtained. Thus, an organochlorosilane production of ca. 800 000 t/a in 1991 corresponds to a

siloxane output of ca. 400 000 t/a. Actual sales are higher due to formulation of silicones with fillers, solvents, and auxiliary chemicals.

The sales of > 600 000 t/a of silicone products in 1992 represented a business volume of ca. $ 5.5×10^9. The United States is the largest market (ca. 40 %), followed by Europe and Japan.

All economically important regions of the world have integrated silane – silicone production facilities. The individual producers are as follows:

United States:	Dow Corning
	General Electric
	Union Carbide
	Wacker (no silane production)
Germany:	Bayer
	Goldschmidt (no silane production)
	Hüls
	Wacker
France:	Rhône-Poulenc
United Kingdom:	Dow Corning
Japan:	Shin Etsu
	Toray Silicones
	Toshiba Silicones

Brazil, Mexico, Italy, Spain, China, the CIS, and India also have production facilities for silicones and in some cases organochlorosilanes, which however are far less important than those in the United States, Europe, and Japan.

1. Introduction

The importance of silk as a renewable raw material for textiles and other goods cannot be appreciated from its minute weight-based share in the world fiber production, but rather from its value in trade and processing. Despite the triumphal advance of synthetic fibers, silk maintains its place in the raw material market, in the textile and clothing industries, and in retail trade because of its unique properties.

Silk has played an important role not only in political, cultural, and economic history (Silk Road, national costumes), but also in the history of technology (textile machines, Jacquard) and in science (protein chemistry, genetics, and genetic engineering).

1.1. Definitions [13]

The term silk generally refers to the thread spun by certain caterpillars, spiders, and mussels. Only silk spun by the larvae of the silk moth in the form of threads that form a cocoon is of practical importance.

According to DIN 60 001 [14], silk is a natural fiber, classified under the term animal fibers. A distinction is made between fibers from the cocoon of the mulberry silk moth *Bombyx mori* L. (mulberry silk) and those of the wild tussah (tussah silk): Chinese (*Antheraea pernyi* guerin); Japanese (*Antheraea yamamai* guerin); and Indian (*Antheraea mylitta* drury, as well as *Actias selene* HBN.). Other wild silks are Indian eri silk (*Samia ricini* Bsd.) and Indian muga silk (*Antheraea assamensis* Ww.).

1.2. History [15, 16]

According to WIEDEMANN [15], sericulture and the processing of silk fibers have occupied an important place in the cultural history of China for about 5000 years.

There is no doubt that the mulberry silkworm was first domesticated in China. All historical records confirm that this country was the cradle of sericulture. A broken cocoon shell and remnants of silk, velvet, ribbons and other fabrics were found in neolithic sites in the Shanxi and Zhejiang Provinces. These remnants were traced back to 2750 – 2850 B.C. by carbon-14 dating. Further research proved that sericulture was thriving at that early stage along the Huang He and Chang Jiang (Yellow and Yangtze Rivers). During the Shang Dynasty (16th Century B.C.), sericulture and weaving techniques attained high levels.

During the Western Han Dynasty (206 B.C. to 8 A.D.), Chinese sericulture entered its golden

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_095

age, and weaving and printing were developed to a high degree of perfection.

During the reign of Han Wudi (140 – 87 B.C.), large amounts of silk were carried over the "Silk Road" from Xi'an, Shaanxi to the Phoenician parts of the eastern Mediterranean, from where they were shipped to all major cities of the west.

Nevertheless, it took some centuries for sericulture to become known in Europe because the Chinese dynasties tried to keep it as a secret. Silk cultivation was established for the first time in 552 A.D. in Byzantium under Emperor Justinian. Byzantium remained the largest silk market in Europe until the 11th century. The spreading of silk is also associated with the advance of the Arabs into the western world (e.g., into Spain). It was not until the end of the 16th century, however, that sericulture became established in Europe, especially in Italy and Southern France.

1.3. Life Cycle of the Mulberry Silkworm [17]

As with other moths, the metamorphosis of the silk moth [7] involves the following four stages: egg, larva (silkworm), pupa (chrysalis), moth. After mating, the female lays flat eggs (up to 500) that are as large as a poppy seed. Larvae ca. 3 mm in size hatch from the eggs in spring after wintering for several months. Normally, they live on the fresh, tender leaves of the mulberry tree (*Morus alba*), although nowadays there are also artificial diets available for raising silkworms. In the following four to six weeks, the larva increases its weight many times by consuming ca. 30 g of mulberry leaves. After molting four times, it reaches a length of ca. 8 – 9 cm and begins to spin a protective cocoon. The silk-producing glands are two long tubes of variable thickness. Each gland consists of an anterior, middle, and posterior section. Fibroin is expressed in the posterior section via the usual DNA – RNA protein pathway and is stored in the middle section. Sericin is synthesized in the middle section and accumulates in a layer around the fibroin core. Fibroin and sericin move into the anterior section, which tapers and combines with the second gland to form a single duct leading into the spinneret. On extrusion in air, the aqueous solution of proteins hardens to form a solid silk thread made of two fibroin filaments surrounded by a cementing layer of sericin. The conversion of liquid fibroin to partly crystalline, fibrillar fibroin (crystallite content ca. 60 %) results from the rearrangement and orientation of the folded fibroin molecules caused by extrusion stress and by stretching exerted on the thread by the head of the larva [8].

During the spinning process, the larva moves its head in a figure-of-eight form, producing ca. 60 cm of thread per minute. The finished, spun cocoon is spherical, oval, or constricted in the middle and hangs in the previously spun pupal bed. From the pupa formed after the last molting, a moth emerges after about one week and leaves the cocoon, which has already been softened by the secretion of a proteolytic liquid and made permeable at one spot. The moths, which have a life span of only a few days, mate shortly afterward, and the females lay their eggs, completing the life cycle of the silkworm.

2. Structure and Properties [1–13]

As a protein fiber readily available in pure form, silk has long been a popular subject of research in microscopy, in analysis of the crystal structure of multiphase systems, and in elucidation of the chemical formulas of proteins.

2.1. Hierarchy and Crystal Structure [18]

The raw silk thread (bave) has a slight lengthwise striation and consists of two round to trilobal, on average 10 – 14 μm fibroin filaments (brins) embedded in sericin or silk gum (Fig. 1). Thus, raw silk has a "sheath-around-two- cores" composite structure.

The hierarchy of a fibroin filament, consisting of fibrils, microfibrils, and polymer molecules, is shown in Figure 1 [19].

As with cultivated silk, the tussah larva spins two filaments simultaneously in a sericin matrix. However, the 25 – 30 μm filaments have a much flatter cross section than those of cultivated silk, and the fibroin-to-sericin ratio is much higher. The bound filament pair or bave

is approximately 1.2 – 3.3 denier, and the filaments exhibit lengthwise striations because of the gum channels in the interior [20].

Figure 1. Texture of silk thread [19]
Reprinted from [19] by permission of the author (slightly modified)

Silk is a highly oriented crystalline fiber [21]. MARSH et al. have postulated a structure for the crystalline regions of silk fibroin [22] in which the polypeptide chains have an antiparallel pleated-sheet conformation and are oriented such that in any one sheet, all the glycyl residues project on one side, and the alanyl and seryl residues on the other. The sheets are then packed so that the glycyl surfaces are in contact, leading to an alternation in intersheet spacing between 0.35 and 0.57 nm. This structure with pleated-sheet molecules arranged in an antiparallel manner and polar projections of the side chains has been widely accepted. However, in 1991, TAKAHASHI et al. [23] proposed a new model in which the pleated sheet molecules are packed in an antipolar manner (Fig. 2).

A more recent analysis of the crystal structure of silk was based on 35 newly observed X-ray reflection intensities. The amino acid sequence in the crystalline region of silk fibroin is $-(\text{GAGAGS})-_n$ (G = glycine; A = alanine; S = serine), which is first approximated as $-(\text{GA})-_n$. The fiber period was estimated to be 0.698 nm. The observed reflections can be indexed by a rectangular unit cell with the parameters $a = 0.938$ nm, $b = 0.949$ nm, and c (fiber axis) = 0.698 nm and the space group $P2_1$-C_2^2.

The crystalline region is composed of a rather irregular stacking of sheet structures formed by hydrogen bonds in which the pleated sheet molecules are arranged in an antiparallel manner (antipolar), different from the polar arrangement proposed by MARSH et al. [22].

2.2. Chemical Composition [5,7,8]

Silk fibroin accounts for 75 – 83 wt % of raw silk. The content of sericin, which surrounds the two fibroin filaments, varies from 17 to 25 %, depending on the species, origin, and culture conditions of the raw silk. Fibroin and sericin are proteins. Waxes and fats (ca. 1.5 %), as well as colorants and mineral components (ca. 1 %), occur exclusively in the gum layer. The colorants include xanthophyll, carotene, and flavones. Small amounts of amino sugars have also been detected [24].

Fibroin. Of the 20 amino acids involved in the chemical composition of fibroin from *Bombyx mori* (see Table 1), four of them – glycine, alanine, serine, and tyrosine – make up > 90 mol %. Fibroin contains very little cystine. Alanine is the most common amino acid in tussah fibroin.

Table 1. Amino acid composition of fibroin and sericin (in mol %) [5]

Amino acid	Fibroin	Sericin
Glycine	44.5	14.7
Alanine	29.3	4.3
Serine	12.1	37.3
Tyrosine	5.2	2.6
Valine	2.2	3.6

To determine the molecular mass of silk fibroin (370 000), aqueous fibroin dispersions of the secretion from the posterior glands of the silkworm are analyzed.

According to KIKUCHI et al. [25], the majority of silk fibroin molecules produced by *Bom-*

Figure 2. Antipolar – antiparallel (AA) fibroin model for the sheet structure formed by hydrogen bonds [23]
The pleated sheet is seen perpendicular to the sheet. In the antiparallel sheet, the up-and-down molecules alternate, and the methyl groups or hydroxymethyl groups (black circles) of the alanine or serine residues, respectively, alternately point to both sides of the sheet along the hydrogen bond direction (hydrogen atoms not shown).

byx mori consist of one heavy (H) chain and one light (L) chain, linked by a single disulfide bond.

Sericin. The secretion with which the larva bonds the two fibroin filaments that come out of the glands is a protein or protein mixture with rubber-elastic properties. It can be dissolved in hot soap solution, alkali solution, or by enzymes. A comparison of the amino acid data of sericin and fibroin (see Table 1) shows that these two components have different compositions; the most frequently occurring amino acid in sericin is serine.

Several authors subdivide sericin in different types based on their solubility in hot water or buffer solutions. Sericin was either isolated from ready spun raw silk filaments [24, 26–28] or from the silk glands of *Bombyx mori* [28, 29]. Dependent on the experimental conditions two [24, 26], three [27], four [28], or five [29] different sericin fractions were obtained. Whether these fractions are really different types of sericin proteins or in part hydrolysis products of sericin, is not definitely known yet [51, 30]. Furthermore it is not known, if all types of sericin isolated from the silk glands also occur in the ready spun raw silk filament [29, 30]. Molecular masses between 1.6×10^4 and ca. 3×10^5 were determined for sericin proteins [28].

2.3. Properties

In the case of fibers, the geometry, the texture, and the mechanical, physical, and chemical properties largely govern mechanical and chemical processing (spinning, weaving, and knitting – preparation, dyeing, printing, and finishing). Much attention has been paid in the literature to the description of silk fiber properties, partly because of the exceptional variety of outward forms. Review articles can be found in [1–13].

The single filaments of degummed silk (i.e., after removal of the sericin, see Section 4.1) have a fineness that varies between 1 and 3.5 dtex depending on its origin. At 3.5 to 4.5 cN/dtex raw silk exhibits, under standard conditions (20 °C, 65 % R.H.) a tensile strength (based on fineness) that almost reaches the values of synthetic fibers. The wet tenacity is 75 – 95 % of the tenacity under standard conditions. The elongation under standard conditions is 18 – 25 %, and in the wet state 15 – 60 %. The corresponding values for degummed silk are a little lower and they de-

pend on the degumming method and the testing conditions (see Sections 2.4 and 4.1) [32]. In addition to its fine and characteristic handle (feel), degummed mulberry silk has good elastic properties.

Silk is hygroscopic. Under normal atmospheric conditions (20 °C, 60 % R.H.), degummed silk absorbs about 10 % water based on the weight of the water-free fiber. The silk trade calculates with 11 % water (regain).

At 1.6 % (longitudinal direction) and 18.7 % (crosswise), fiber swelling is strongly anisotropic. Silk has a relatively high electrical resistance. At low air humidity, it becomes electrostatically charged when subjected to friction.

Silk is virtually unaffected by temperatures up to 140 °C; above 150 °C, thermal decomposition occurs.

Along with wool and the synthetic textile fibers polyester and polyamide, silk is a poorly inflammable fibrous material [33].

As a protein, silk fibroin is a polyampholyte with cationic and anionic side chains and, therefore, absorbs strong alkalis and mineral acids with the formation of salts. The isoionic point is at pH 5.0. Moderately strong and weak acids undergo primarily molecular bonding to silk via hydrogen bonds.

In the isoionic range (pH 4 – 5), swelling and reactivity are at their lowest.

The degree of decomposition of silk after chemical textile operations is measured mechanically (tenacity and elongation) and chemically (viscometric determination of the molecular mass of silk). The weight loss in blank dyeing is determined indirectly from the amount of silk fibroin that has dissolved (nitrogen analysis).

In comparison with wool, silk is more sensitive to acid because of the virtual absence of acid-stable cystine bridges. However, the absence of alkali-sensitive cystine bridges gives silk a higher resistance to alkali. For this reason, silk can be treated with 16 – 18 % sodium hydroxide solution (mercerizing bath) at low temperature to produce crepe effects in mixed fabrics containing cotton yarn in the warp and the weft.

Silk can absorb considerable amounts of salts, a property that is exploited in weighting (see Section 4.2). Salts can degrade silk under certain conditions, especially in the presence of light, air, moisture, and perspiration. *Bombyx mori* fibroin is soluble in certain concentrated aqueous salt solutions, e.g., lithium bromide, lithium iodide, lithium thiocyanate, and copper ethylenediamine solutions. The best of these solvents is probably concentrated (49 %) aqueous lithium thiocyanate, because the solution is approximately pH neutral, and the solvent is unlikely to cause peptide bond hydrolysis [34].

Sunlight degrades silk rapidly. Oxidizing agents degrade silk proteins, causing discoloration, the formation of acidic groups, and deterioration of the mechanical properties.

Although chemically similar to cultivated silk, tussah is more resistant to corrosive chemicals (see Table 2). This increased resistance, particularly to alkali, can be an advantage in dyeing. It permits the application of reactive dyes to tussah by means of an alkaline fixation procedure [20].

Table 2. Dissolution time of silk in chemicals [20]

Treatment	Cultivated silk	Tussah
Boiling 1 % NaOH	rapid	30 – 60 min
Cold concentrated HCl (*d* 1.16)	rapid	very slow
$ZnCl_2$ solution (*d* 1.67)	rapid	slow

2.4. Analysis

The sericin content in incompletely degummed silk is determined gravimetrically after high-temperature alkaline extraction of sericin. It can also be determined by amino acid analysis or from the sum of the primary amino groups [35].

When silk is heated in acids or alkalies, losses in tenacity occur. The greater the losses in tenacity are, the lower is the molecular mass of the silk fibroin. This can be determined by measuring the viscosity of a solution of silk in lithium bromide solution [36].

Blends of polyester with silk or wool are commonly analyzed by using a boiling solution of 5 % sodium or potassium hydroxide to dissolve the protein fiber. A faster room-temperature technique using a trichloroacetic acid – dichloromethane reagent to eliminate the polyester in 5 min has been proposed as a reliable method for determining the protein fiber content [37].

The comfort and handle of silk fabrics are tested by the methods of Kawabata [38, 39].

Silk that has been graft polymerized with methacrylamide (see Section 4.2) can be identified by solubility tests or IR spectroscopy [40].

3. Production

3.1. Sericulture [6,11]

The silk industry is closely tied to cultivation of the mulberry tree. Although it is also possible to rear silkworms on an industrial scale by using completely or partly artificial diets [11,41], the cultivated silkworm, *Bombyx mori*, usually is fed by mulberry leaves. The life cycle of the silk moth is linked to the cycle of the mulberry tree. Since young silk-worms require young leaves to eat, the hatching of the eggs is timed to coincide with the appearance of new leaves.

The lives of the silk farmer and his family and employees are dominated by the silkworm. From the time of hatching until the spinning of the cocoon, the larva eats prodigiously. Since the larvae from 30 g of eggs (40 000 – 60 000) consume about one tonne of leaves during their lifetime of 35 d, much time is spent in picking and preparing leaves. Young silkworms require chopped leaves, which adds to the work. In addition, the trays on which silkworms are raised must be cleaned daily. After they have been laid, the eggs must pass through a period of low temperature before they will hatch. This tendency is a holdover from the time when the silk moth was a wild insect that laid its eggs in the fall for hatching in the following spring. Cultured silk eggs are exposed to artificial low temperature for a period of time.

The reproduction of eggs is distinctly separate from the farmer's activity of rearing cocoons. These two phases are kept separate because of the many precautions that must be taken not only to prevent the introduction of diseased eggs and keep the silk produced of high quality, but mainly to avoid degeneration by inbreeding.

The silk farmer receives his eggs on cards. About a week before the mulberry trees bring forth their first leaves, the cards of eggs are placed in an incubator at 27 °C. The eggs hatch in about ten days.

A large number of breedings of *Bombyx mor*i exist. They differ in thickness and length of the thread spun by the silkworms, in their demands and adaptation towards climate and diet.

Tussah silkworm growing is quite different from the cultivation of mulberry silkworms. Whereas mulberry silkworms are raised indoors, tussahs grow in toothed-oak forests. After baby tussah worms have hatched in early spring, the cultivators bring them to oak forests in hilly areas and place them around tree trunks. The wild silkworms then begin to climb the trees and feed on the leaves. To prevent the silkworms from being eaten or harmed, their cultivators fire a shotgun into the air at intervals to scare birds away. The cocoons are harvested from the trees in autumn [42].

3.2. Production of Silk Thread

To permit the storage of cocoons over a longer period of time, the pupae contained in the cocoons are first killed with hot air or superheated steam.

In the sorting department, the well-preserved cocoons are separated from the faulty ones (damaged, pierced). After the loose floss silk has been removed, the cocoons are sorted according to size, color, and evenness. Cocoons of the same breed season, class, and size are mixed to obtain an even batch.

In the filature (silk-reeling factory), 40 – 60 cocoons are placed in a small basin filled with boiling water. The cocoons are lightly beaten by means of an alternately rotating besom and kept below the surface of the water. The silk gum softens, and the outer layers of the cocoon that cannot be reeled (floss silk) is removed. The cocoons prepared in this manner, which have exposed, reelable thread ends, are now placed in the reeling basin (water temperature ca. 40 °C). The threads from several cocoons (the number depends on the titer desired) are drawn off together and wound into a hank (grège or reeled silk). The hanks are then dried.

Depending on the origin and species, the total length of thread in a mulberry silk cocoon is 1000 – 3000 m, only 500 – 1500 m of which can be reeled. To obtain 1 kg of grège, 5 – 10 kg of cocoons are required, depending on the technological standard in the particular country.

Together with the waste from silkworm raising – watt silk, defective cocoons, pierced co-

coons – the outer and inner layers of the cocoon that cannot be reeled off are processed into high-quality schappe and bourette silk. Oils and fish feed are produced from the pupae.

Unlike cultivated silk, tussah is very difficult to reel off without preliminary bleaching of the cocoons with a weak solution of hydrogen peroxide and sodium silicate [20].

3.3. World Production

In 1998, the worldwide production of raw silk amounted to ca. 70 727 t. The most important silk-producing countries are China, India, Japan, Brazil, and Uzbekistan (see Table 3).

World production of wild silk is estimated to be 10 – 15 % of the production of mulberry silk. The largest exporter of raw silk is China. In China, the income of about 100×10^6 people is based on silk production or finishing [43].

Silk has less than 0.2 % of the total world fiber market. At present, silk is produced in about 50 countries and the number is continuously increasing. New silk producing countries are for instance Ivory coast, Uganda, and Colombia [44].

The data in Table 3 show that silk production rapidly increased from the beginning of the 1990s until 1995, and then a strong decrease occurred. This was due to the diminished demands of the consumers for silk and to the overabundance of silk products on the world markets. The image of silk has been downgraded for several years as a result of the marketing of very cheap made-up goods from China and India, i. e., since the launching of poor quality ″sand-washed silk″ [45]. The official Chinese price for raw silk (grade 3A, 20/22 denier) is today (1998) about $ 20 per kilogram (ten years ago $ 51).

3.4. Silk Yarns – Classification and Testing

Fine silk yarns for weaving are divided into two groups [46]:

1) Filament yarns made from raw grège: grège, tram, organzine, crepe, and grenadine
2) Spun yarns such as schappe silk made from the waste from cocoon processing and bourette silk made from the waste from schappe spinning

The fineness of grège threads is expressed in denier (grams per 9000 m) or dtex (grams per 10 000 m) and that of spinning fiber yarns in Nm (metric number = length in meters of 1 g).

According to the International Silk Association (Lyon), the standard classification for grège threads involves the following 12 quality classes: 6A, 5A, 4A, 3A, 2A, A, B, C, D, E, F, and G. Class 6A represents the best quality, which is rarely attained; G is the lowest grade. The quality normally found on the market is 20/22 den, 3A and 4A.

Silk threads are tested objectively and subjectively.

Objective testing includes tests for titer, size, tenacity, elongation, cohesion, and winding breaks, as well as determination of moisture and sericin content [11,47,48].

Subjective tests include the seriplane test, in which grège threads are wound on black board (seriplane) and the evenness, cleanness, and neatness are evaluated visually. However, this is being increasingly performed by electronic testing [11,48].

Many silk producing countries have their own systems for classification of raw silk quality. The Chinese classification system is the most important one, because the lion's share of silk is produced in China. The countries of CIS and Brazil use quite similar systems. Classification is mostly carried out by subjective-visual assessment and therefore the reproducibility is not good. The Chinese classification system for grège threads involves the following 12 quality classes: 6A, 5A, 4A, ..., 2A, A, B, ..., F and substandard. Class 6A represents the best quality; substandard is the lowest grade.

The International Silk Association (ISA, respectively AIS - Association Internationale de la Soie) competes for the introduction of a new international raw silk classification system, based on the tex-system and reducing the 12 (Chinese) grades to 8 grades. Classification can be carried out either by the traditional "Seriplane test" (subjective, visual assessment of evenness, cleanness, neatness; with the grades S6, S5, ..., S0, Ssub) or by electronic testing methods (automated testing of titer, size, evenness, thick and thin defects, impurities, tenacity, elongation, co-

hesion and winding properties; with the grades E6, E5, ..., E0, Esub) [48].

4. Processing

4.1. Degumming [7,35,49–51]

The term degumming (boiling-off) refers to partial or complete removal of the sericin that covers the two fibroin filaments. The sericin sheath is responsible for the brittleness, harsh handle, mat appearance, and yellowish to yellowish green color of raw silk. Only after degumming does silk attain its full gloss and its soft, smooth feel, which can be improved further in a finishing process following dyeing. Degumming results in a weight loss that can amount to 2 – 30 %, depending on the desired degree of degumming.

Most fabrics are degummed in the producing countries. The degumming agent used is still mainly Marseilles soap, an alkali-free olive oil soap. In this classical degumming method, silk is treated in a soap bath at 90 – 98 °C for 2 – 4 h, depending on the quality and type of fabric. It is then boiled off again and subjected to weakly ammoniacal rinsing. In the case of tussah silk, alkaline boiling off with soap and soda removes the gum adequately because of the low sericin content. Other degumming methods use enzyme solutions (e.g., papain, trypsin, or various bacterial enzymes), boiling water under pressure, weakly alkaline solution ($NaHCO_3$, ammonia), or acidic solution [52] (e.g., tartaric acid or citric acid). The degumming process can be accelerated by treatment with ultrasound [53,54].

New degumming methods have been developed to save time, water, and energy in the production process. The latest powder products consist mainly of sodium salts, such as phosphates and carbonates, sometimes with a soap additive. In addition to sodium salts, liquid scouring agents also contain anionic surfactants and other organic substances such as sequestering and fiber-protective agents. In contrast to soap, these newer products can be used in continuous processes [55,56].

The degree and evenness of degumming of silk can be evaluated qualitatively by means of a dyeing test with C.I. Direct Red 80 [35]. In contrast to fibroin, the sericin present is dyed red. Even degumming must be achieved because

otherwise levelness problems could arise during dyeing.

Raw silk is degummed either as yarn in the form of hanks in an open beck, in a foam degumming machine or on perforated tubes, or as fabric in a star machine, winch beck, jigger, or continuous machines (e.g., open-width washing machine). In principle, any dyeing machine can be used. The time required to degum silk fabrics depends on the weight of the fabric. New machines for degumming, washing, and dyeing of all spool yarns and star-hung fabrics which operate at ambient or high temperatures are now commercially available.

4.2. Weighting [7,49,57]

Weighting of silk refers to the incorporation of metal salts, plant materials, or synthetic substances into fibroin to compensate for the loss in weight during degumming. Moreover, increased fiber volume and improved luster and handle are achieved in this process. Hanks are usually weighted before dyeing, in vats, on sticks, or in special centrifuges, hank-washing machines, or continuous open-width washing machines.

The weighting agent is fixed so that it is washfast. Weighting with water-soluble compounds such as dextrin increases the weight without producing a permanent improvement in fiber properties.

Today, tin phosphate silicate weighting (mineral weighting), a method known for decades, plays only a minor role. Silk is treated in succession with aqueous solutions of tin(IV)-chloride and disodium hydrogenphosphate. Basic tin phosphate formed in the fiber is subsequently converted to washfast tin sodium silicate in a concentrated silicate bath. The degree of weighting depends on the number of treatments with tin salt and phosphate; increases in weight of more than 100 % are possible. The degree of weighting is based on the weight of raw silk. If weighting compensates exactly for the loss in weight incurred during degumming, the silk is referred to as par. For example, 50 % above par means that the weight of 100 kg of raw silk has increased by 50 kg.

Mineral/plant or pure plant weighting with tanning agents or logwood extract is used principally for material that is to be dyed black. This type of weighting is often combined with black dyeing.

More recent methods use synthetic resins (e.g., methacrylamide) for weighting silk yarns and fabrics. The material is generally dyed first and then weighted by graft polymerization with methacrylamide. This procedure gives improved fastness but can be used only with dyes that are insensitive to graft polymerization conditions [57]. When silk is grafted with methacrylamide, increases in weight of 20 to 35 % are usual.

In general, the degree of weighting depends on the intended use of the silk. However, very high mineral weightings reduce the quality, and the silk becomes brittle and damaged; exposure to sunlight and moisture result in premature wear. Furthermore, the affinity for dyes and the washfastness of the dyed material are reduced. For this reason, silk is weighted today only for certain articles (e.g., ties, borders, embroidery) to improve luster, handle, drape, and fullness.

In comparison with cultivated silk, much less weight is lost when tussah is degummed. Therefore, weighting is of less importance in processing tussah [20].

4.3. Bleaching [7,49]

In most cases, the colored pigments present in sericin are removed during degumming. To achieve clear white tones and brilliant light shades, oxidative or reductive bleaching can be used. Bleaching is usually carried out after degumming.

Reductive bleaching agents that can be used for silk are sulfur dioxide, dithionite, or hydrogen sulfite. Sulfur dioxide is preferred to other reductive bleaching agents because of easy handling, lower cost, and fiber preservation.

However, oxidative bleaching with hydrogen peroxide or H_2O_2-releasing salts is of much greater importance. The resulting whiteness is, in contrast to sulfur dioxide bleaching, persistent and the material is free from odor. The concentration and temperature of the bleaching liquor depend on the amount of colored pigment remaining on the fiber.

Optical brighteners are added to the bleach to achieve full whiteness. This step is usually performed in a reductive bleaching liquor after oxidative prebleaching.

For silk piece goods, degumming and bleaching are often carried out in the same bath. Since bleaching damages the fibers less than mineral weighting, bleaching is usually performed after weighting. Because of its intense inherent color, which cannot be removed even by complete degumming, tussah silk requires considerably stronger bleaching conditions than mulberry silk. Depending on the quality of tussah, full whiteness can be achieved only with great difficulty, and fiber damage is unavoidable [58].

4.4. Dyeing [7,59]

As a protein fiber, silk can be dyed with almost all types of dyes used for wool dyeing; acid, basic, metal-complex, reactive, and vat dyes, as well as pigments (see → Textile Dyeing). Also older natural dyes such as logwood and tanning agents are still used. The fastness required often determines the choice of dye. Acid dyes are the most frequently used dyes for both hank silk and piece goods because they give good to very good lightfastness, and an extensive range of colors is available. Although basic dyes give glossy, clear colors, the lightfastness is lower. However, the levelness can be improved by adding acetic acid, and the wetfastness can be improved by aftertreatment with tannic acid solution. Preformed chromium complex dyes with good leveling ability produce high wetfastness and lightfastness. The 1:2 metal complex dyes are also used in silk dyeing.

Although vat dyes produce washfast colors, they cause considerable fiber damage when exposed to strong light (e.g., decorative materials and drapes). Weighted silk cannot be dyed with vat dyes because the weighting of the thread would be removed by the alkaline dye liquor. Reactive dyes give good results, especially when used under alkaline conditions. In many cases, dyeing with reactive dyes leads to additional fixation of the dye to the fiber through covalent bonding with the numerous functional groups present.

For blackening, logwood black or tanning agents are still being used because they give a special depth of color and filling effect. The 1:2 metal-complex, afterchrome, and Naphtol AS dyes can also be used to produce deep black tones.

In comparison with wool, silk exhibits a markedly lower affinity for wool dyes, especially for reactive dyes. This is due to the high orientation of fibroin, impeding the insertion of dyes into the filaments [60] and the lower acid-binding capacity of silk compared to wool [49, 61]. Due to its fine titer, about twice the amount or, in the case of tussah, almost three times the amount of dye is required to achieve the same depth of color as obtained with wool [13,62, 63]). As a rule, degummed silk is dyed, even degumming being a requirement for level dyeing. The degumming liquor can be used in silk dyeing as an excellent protective colloid and leveling agent.

The dyeing temperature should not exceed 90 °C because the luster and handle of silk can be negatively influenced on boiling.

The dyeing processes used are the exhaust, cold pad-batch, and the pad-steam methods. The exhaust dyeing process is the most important because it can be used for dyeing piece goods and all types of yarn.

In principle, all dyeing machines employed for other textile fibers can be used for silk. The machines must be modified because of the sensitivity of silk to tensile force and mechanical stress. Silk is dyed in hank (yarn) form on perforated tubes or in piece form. The dyeing aggregates used for yarn dyeing are the hank-dyeing machine, package dyeing apparatus, and spraying arm dyeing machine, and those used for piece dyeing are the star frame, winch vat jig, beam, and jet dyeing machine.

4.5. Printing [7,64]

Textile printing is particularly important in silk finishing. Based on total silk production, the percentage of printed articles is higher than for all other natural and man-made fibers.

Articles produced by silk printing are predominantly dress materials, scarves, shawls, ties, and increasingly, drapery and upholstery fabrics.

Like dyeing, printing also requires the even degumming of silk. If necessary, unevenly degummed fabric must be improved in a rewashing step. For yarn-dyed articles, a prewash is helpful to prevent bleeding during the rewashing process.

Silk fabric made from nonweighted silk is generally used for printing. In the printing of mineral-weighted silk, the weighting should not exceed 15 % above par because otherwise the material becomes brittle on steaming, and color changes occur during discharge printing due to the formation of tin sulfide. Both direct printing and discharge printing are suitable. As with other fibers, special effects can be achieved by the application of pigment, matte white, lacquer, and bronze printing to silk, sometimes in combination with direct and discharge printing.

Generally, silk prints are produced with the same types of dyes and printing methods as wool prints (see → Textile Printing). For reasons of fastness, acid, metal- complex, and reactive dyes are preferred; in addition to these, vat dyes can also be used for discharge printing.

Silk printing is carried out mechanically as hand screen printing or machine printing (automatic flat screen and rotary screen printing machines).

4.6. Special Finishing [7,65]

Objectives of special finishing processes are to improve some rather unfavorable properties of silk (creasing properties, launderability, UV and light resistance), if possible, without damaging the characteristic luster and handle of silk.

Because of the high price of silk and low percentage of worldwide annual fiber production, relatively little attention has been paid to the development of special finishing processes. For instance, both wet tenacity and water-drop fastness can be improved by treatment with hexamethylenetetramine (as a source of formaldehyde for cross-linking). Fabrics finished with polyurethanes exhibit good wet crease recovery and are dimensionally stable on washing. Cross-links resulting from the reaction with dihydroxymethyl urea or thiourea confer a higher crease resistance on silk but do not improve its tenacity. Silk that has been treated with hydroxymethylacrylamide and tin chloride shows increased wet and dry crease recovery. Finishing with mono- and multifunctional epoxides can improve moisture uptake and pleat retention. An effective flameproof finish results from reaction with phosphoric acid derivatives and quaternary ammonium salts.

At the moment, sand-washed silk fabrics are highly fashionable. The sand-washing process is a special washing procedure for silk fabrics to produce a certain degree of fibrillation with an acceptable degree of loss of tenacity. Sand-washed fabrics have a special appearance and handle and a higher surface roughness than "normal" silk. In 1997, 70 to 80 % of the silk fabrics produced in China were finished with sand-washing processes [66].

Other finishing processes serve for scrooping, softening, and building up a light, firm handle [49].

Schappe articles are treated in order to improve the slippage behavior. Tussah articles are made water repellent by special finishes.

5. Uses and Other Aspects [13,15]

The uses of silk cover a wide range of applications from ready-to-wear articles and home textiles to technical fabrics and cosmetic articles. Ready-to-wear articles include mainly mens' and womens' wear such as shirts, blouses, scarves, shawls, ties, and high-quality evening clothes, as well as lining materials, underwear, night clothes, national dress (kimonos and sarongs). In home textiles, silk is most often used for furnishing fabrics, upholstery, wallpaper, velvet, plush, carpets, and covers. In technical fabrics, silk is employed for typewriter ribbon, insulating material for cable covering, and surgical articles. Silk powder is added to lipstick, skin cream, and soap; fibroin or sericin is added to shampoos and lotions.

Silk is also a very suitable material for sewing and embroidery thread because it can be dyed to give any shade.

According to the German textile labeling law (Textilkennzeichnungsgesetz, TKG), the name silk is permitted only for fibers that are isolated from the cocoons of silk-spinning insects (mulberry silk and wild silk). The trademark for fabric made of 100 % fine or wild silk is awarded by the International Silk Organization in Lyon (see Fig. 3). In this context it has to be mentioned that according to the TKG and the corresponding European guideline no special labeling is necessary for weighted silk. The fabrics may be traded as "pure silk".

Figure 3. International silk symbol

The silk atlas describes 150 different silk fabrics. Of these, nine are mentioned here with their main applications:

Crêpe Georgette (for evening dresses, blouses), crêpe de Chine façonné (for ladies' dresses, blouses), satin crepe (for blouses, evening dresses, negligees), faille (for dresses, coats), taffeta (for robes, frills, cocktail dresses, blouses, lining), honan silk (for sports clothes, two-piece outfits), organdy (also organza; for bridal dresses, blouses, ladies' hats), toile de soie (for blouses, shirts), and doupion fabrics (blouses, dresses) [15].

According to Mecheels [67], the thermophysiological wearing comfort of silk textiles is very high because silk material is very agreeable to the skin, and the water balance seems to be optimal.

Clothes made of silk function excellently under everyday conditions, even when they come in very close contact with the skin. The same applies to their appearance when worn and the drape of silk clothes. However, some drawbacks must be accepted. Silk materials are highly sensitive to abrasion owing to the fibrillation of the fiber surface, which is exploited in sand-washed schappe fabrics. The wearing time of silk clothes is limited by abrasion and perspiration damage. The low resistance of silk to light and the insufficient lightfastness of some colorants can lead to the yellowing of natural- color areas and color changes in silk outer clothing.

As a rule, the drycleaning of silk clothes poses no problems if specific conditions are maintained. Depending on the type of fabric and degree of fastness of the color or design, silk articles can also be washed. However, the manufacturer's instructions for care should be followed.

No health risks are involved in wearing silk clothes, even if they come in direct contact with the skin. Allergies are observed very rarely and are caused not by the silk itself, but by substances added during finishing (see Chap. 4). On June 6, 1991, a seminar was held in Hof (Germany) on the medical compatibility of chemically finished textiles and the following statement was made [68]:

"Properly finished and treated textiles represent no health risk for humans.

Long-term studies at the Dermatological University Clinic in Erlangen have clearly shown that real allergies to finished textiles for clothing are extremely rare, even when formaldehyde and individual disperse dyes are included.

The possible allergenic potential for sensitive persons can be eliminated by following the recommendation to wash textiles before use.

Properly finished and dyed textiles exert no carcinogenic effect."

More recent studies also draw the conclusion that allergies and other health risks caused by wearing textiles are extremely low [69, 70].

Today, silk garments are often priced in the same range as garments made of cotton or synthetic fibers. As already mentioned in Section 3.3, the image of silk has suffered a lot in the last ten years due to the overabundance of low-price, low-quality made-up goods on the markets. As a result, silk is not unreservedly associated with luxury and exclusiveness any more. Nevertheless, the upgrowing standard of living in Southeast Asia and increasing demands for comfortable clothes made of natural, ecologically friendly processed fibers permit a confident prognosis for the consumption of silk in the future. In order to refine the image of silk, efforts are made to assure certain standards of quality during all stages of silk processing.

Acknowledgments. The authors would like to thank Ursula Behn (Deutsches Wollforschungsinstitut) for revising the manuscript and K.-H. Phan (Deutsches Wollforschungsin-

stitut), ADOLF FAES (President of the International Silk Association, Zürich), B. TRUDEL (Trudel Limited, Zürich), R. CURRIE (General Secretary of the International Silk Association, Lyon), R. CREMER (Verband der Deutschen Seiden- und Samtindustrie, Krefeld), H. FREI (Siber Hegner Textil AG, Zürich), L. ZOSSO (DESCO von Schulthess AG, Zürich), Mr. SCHWARZENBACH (Schubiger & Schwarzenbach, Uznach/Switzerland), E. IIZUKA (Shinshu University, Ueda, Nagano/Japan), S. MIZUNO (Tohoku University, Sendai/Japan) and Y. Takahashi (Osaka University, Osaka/Japan) for valuable contributions and information.

1. History [19]

1.1. Centers of Silver Production [1–6]

Ancient Times. Like gold, silver occurs in native form and therefore has been known to humans since prehistoric times. The oldest finds of silver whose age can be determined date from around 4000 B.C. in Egypt (see Fig. 1). In the following years, silver appeared in the entire cultural region of the eastern Mediterranean. In the second millennium B.C., the Phoenicians obtained large quantities of silver from deposits on the Iberian Peninsula, which were distributed by their companies of traveling merchants.

The first upsurge in the production of silver took place when the Greeks exploited the mines of Laurion, which reached their peak productivity in ca. 500 B.C. The Greeks also worked silver mines in Thrace, Asia Minor, and the entire Aegean region. The Athenian empire and its claim to power were based to a large extent on the role of silver for coinage. Modern methods of trace analysis have elucidated the relationship between the extraction and processing of the Greek silver deposits and their effects on the political developments at that time [7–11].

Figure 1. Historical survey of important silver production centers and silver processing

Rome was initially poor in silver. However, considerable quantities were soon obtained in the provinces that fell to the Roman Empire (i.e., southern Spain, the Balkans, the Carpathians, etc.). In many Roman expeditions of conquest (e.g., the Punic wars and those in the period of the civil wars), the seizing of silver mines was often a cause of war-like disputes. The introduction of the silver denarius as the common cur-

rency in ca. 300 B.C. elevated the political importance of the national metal.

Undoubtedly, silver was also extracted in pre-Christian times in middle and northern Europe, although this only became known through the Romans' written records. Likewise in India, China, and Japan the production of silver probably dates back to ancient times.

When the migration of the Germanic people began and the political dissolution of the Roman Empire occurred, silver production practically ceased. This situation changed with the reorganization of the western lands by the Carolingians.

Middle Ages. During the Middle Ages, the extraction of silver became widespread in central Europe. Some of the production locations are listed here, with their starting dates: Bohemia (Pribram: 753; Miss: 1137; Kuttenberg: 1240), Sweden (Sala: 8th century), Saxony (Freiberg, which produced a total of 5500 t silver: 1103; Mittweida and Frankenberg: 922), Erzgebirge (Joachimsthal: 1510; Annaberg, Schneeberg), Alsace (Markirch: 7th century), the Lahn region, Siegerland (ca. 860), Silesia (Beuthen, Tarnowitz), Hungary (Schemnitz), Norway (Kongsberg), Tyrol, Steiermark, Salzburg, the southern Black Forest (Freiburg im Breisgau), Harz Rammelsberg, which provided much of Europe's silver in the 11th and 12th centuries: 968; St. Andreasberg; Mansfeld, which was the source of most of the silver produced in Germany at that time: 1450.

Many of these deposits were exhausted by the end of the Middle Ages and often long before this. However, the mines in the Harz, Siebenbürgen, Freiberg, Norway, and Alsace retained some of their importance up to the industrial revolution.

The deposits in India, Japan, China, and pre-Columbian America, were also mined during the Middle Ages.

Modern Times. After the discovery of America, silver was plundered by the Spanish and brought to Europe in large quantities. Also, new deposits were developed. Soon, America was producing more silver than Europe, and prices collapsed. Up to ca. 1700, world production was dominated by Central and South America (Peru, Bolivia, Chile, and Argentina).

In the 1800s, the main center of production moved to North America, i.e., Mexico, Canada, and the United States (Nevada). Also, significant quantities of silver were produced in Russia and Australia, and the output from Europe increased, although by then this was almost entirely associated with lead and zinc ores.

After World War II, Poland became an important producer following the exploitation of newly discovered silver-containing copper deposits.

1.2. Extent of Production

By the beginning of the Middle Ages (ca. 800 A.D.), a total of ca. 50 000 – 100 000 t of silver is estimated to have been extracted. By then the silver deposits of the European Mediterranean region, almost the only regions to be mined in ancient times were effectively exhausted.

At the end of the Middle Ages, world production had almost dropped to 50 t/a. During the whole of the Middle Ages, ca. 200 000 – 300 000 t silver was extracted, most of which came from Europe, mainly the German-speaking area.

By 1975, average world primary silver production ca. $> 10\,000$ t/a, and by 1991, it reached a peak of 11 500 t/a. The countries of North and South America today account for more than two-thirds of world production. In 1975, Poland was by far the largest producer in Europe. For primary production figures, see Table 1.

In total, $(1 - 1.2) \times 10^6$ t silver has been extracted worldwide. This is about 10 times the figure for gold production, 100 times the total world production of platinum, and 50 times that of the platinum-group metals.

1.3. Development of Production Processes [1–13]

Very little has been written about the techniques of silver extraction in ancient times. The Egyptians are thought to have separated gold from silver by heating with salt. They must therefore have known how to convert the silver chloride produced into metallic silver.

Table 1. Silver production excluding CIS and China (t/a)

Region	1989	1991	1992	1994	1996	1997
Mining production	11 481	11 560	11 480	10 650	11 700	12 160
Mexico	2306	2250	2400	2500	2535	2580
United States	2007	1850	1820	1770	1550	1800
Peru	1840	1770	1500	1520	1970	2070

Australia	1168	1180	1080	1100	1150	1160
Other countries	2854	3220	3530	3020	3250	3380
Secondary silver	3344	3380	3450	3300	4030	4170
Total	14 825	14 940	14 930	13 950	15 730	16 330

The main source of silver in ancient times was silver-containing lead ores. In the Middle Ages, deposits of native silver were also important, especially in Central Europe. The rich ores could be smelted simply after hand separation (i.e., after crushing and separating from the worthless rock). Large pieces weighing more than 100 kg, or large blocks weighing many tons and containing native metal, were found and processed in this way.

The Greeks, the Romans, and the miners of the Middle Ages knew how to process silver-containing lead ores by smelting to produce lead. In the Middle Ages, the lead was removed by oxidation in cupellation furnaces to produce silver with a fineness of 650/1000 – 875/1000. This could then be oxidized further to give a fineness of 990/1000.

When the silver was accompanied by copper in the deposit, the liquation process [14] was used. The silver-containing copper was melted with lead, and the silver-rich liquid phase recovered by liquation was blown with air.

Introduction of the amalgamation process in 1566 improved silver productivity and production rates in Mexican and South American mines. This process later became dominant and was used in the United States and, from 1800, in Europe in a modified form suitable for a wide range of raw materials.

After the mid-1800s several new techniques were developed that replaced the old processes or improved economics. For example, the lead cupellation process was made more efficient by introduction of the Pattinson process (1833; see Section 4.2) which for a time was very widely used. This was based on the segregation of solid lead from the lead – silver melt by cooling. This increased the silver content to 2.5 % and thereby decreased the load on the cupellation process. The Parkes process (1850; see Section 4.2) soon replaced the Pattinson process because of its superior economics. In this process, silver was transferred from the lead to zinc floating on the surface of the lead; this formed a crust that could be removed. The Parkes process is still virtually the only process used today for extracting silver from lead ores. It is also used to extract silver from lead – zinc and zinc ores.

The chloridizing roasting of copper ores followed by leaching with brine to dissolve the silver chloride formed was introduced in 1843 by Augustin (see Section 4.3.4); it was soon replaced by sulfation roasting (see Section 4.3.4), at temperatures below the decomposition temperature of silver sulfate and above that of copper sulfate, followed by leaching with water. This was known as the Ziervogel process, and for almost 100 years most of the silver in German ores was extracted in this way. The sulfuric acid extraction of dead-burnt copper ore in a stream of air (see page 16), to form a silver-containing slime, was used for only a short period. After 1856, thiosulfate leaching (see Section 4.1.4) idized roasted ore was used primarily in Mexico and California. In the Patera process, sodium thiosulfate was used; in the Kiss process, calcium thiosulfate; and in the Russel process, sodium copper thiosulfate. Since ca. 1900, cyanide leaching (see Section 4.1.3) is still used for silver ores that are not smelted, has been the most important aqueous treatment process.

Since ca. 1876, almost all the silver associated with copper has been obtained from the electrolytic refining of copper. The silver appears in the copper anode slimes, which are generally treated by pyrometallurgical processes (see Sections 4.3.3, 4.3.4).

To separate silver from the gold in auriferous silver (the end product of nearly all smelting and

hydrometallurgical extraction processes), the nitric acid process (developed in 1433–see Section 6.2) and the sulfuric acid process (dating from 1802–see Section 6.3) have been completely replaced by electrolytic refining.

1.4. Monetary Significance and Price Structure [1,15,16]

From ancient times to the Middle Ages and later, even into the present century, silver was the classic metal for currency. In comparison, gold played an almost insignificant role.

In the 6th century B.C., King Croesus ordered the minting of silver coins. In ancient Greece, silver currency was the basis of the economic system. In 296 B.C. the Romans introduced the silver denarius as the general method of payment, and gold ceased being used in coins from 217 B.C. Silver was the basis of the coinage reform by the Byzantine Empire in A.D. 310, and was recognized throughout the Mediterranean region, so that silver maintained its importance as a coinage metal for many centuries. Charlemagne made silver the basis of the currency system of his empire.

During the last two centuries, gold began to displace silver, mainly due to the reduction in the price of silver caused by the surplus from new production, as well as the demonetization of silver.

Between the two world wars, strong moves, triggered by inflation and the world economic crisis, were made to remonetize silver, but these largely came to naught.

After World War II, because of the increasing demand and the shortage of supply, the price of silver rose so much that by 1970 the value of the silver in the most important silver coins still in circulation (U.S. dollars and Swiss francs) exceeded the face value of the coins. Silver was therefore virtually completely demonetized.

After the 17th century, the ratio of the prices of silver and gold remained fairly constant at ca. 1 : 15 for a long period. However, free price movements have continually tended to shift this ratio, and it has often been kept constant by state intervention. A fairly gradual increase in the price of gold began ca. 120 years ago. At the beginning of World War I, the ratio reached 1 : 40. During the World War II it rose to 1 : 100, and during the following three decades it fluctuated around 1 : 40. In 1981 it was 1 : 50, and in 1992 it was 1 : 95.

Silver prices have been freely determined by supply and demand from 1970, after which the price rose steadily from ca. 90 €/kg to 150–260 €/kg. In late 1979 and early 1980, speculative dealings of a hitherto unimagined volume occurred, and the price of silver briefly reached nearly 1406 €/kg [17]. In the following decade, and up to the present, a rapid and fairly continuous decline in price has taken place, reaching a low of 8 €/kg in 1992. The price of silver now reflects its status as an industrial metal and depends on the current economic situation. In parallel with this, silver has lost its importance as an investment metal. The high stock levels (see Chap. 12) and sales of these stocks from time to time also affect price reductions.

2. Properties [18–24]

Silver [*7440-22-4*], like gold and the platinum-group metals, is a noble metal. Silver, gold, and copper are known as the coinage metals.

2.1. Atomic Properties [25]

Silver has an atomic number of 47 and a relative atomic mass of 107.8682. Natural silver consists of the stable isotopes ^{107}Ag (51.8 %) and ^{109}Ag (48.2 %). Many artificial isotopes with relative atomic masses between 102 and 117 are known.

The electronic configuration of silver is [Kr]$4d^{10}5s^1$. The $5s^1$ shell is the principal valence orbital, which accounts for the preference for oxidation state 1. The $4d$ shell can also act as a valence orbital, resulting in oxidation states 2 and 3. Thus, silver behaves as a transition metal due to the contribution from the inner valence orbital. Since the differences between the energies of the valence electrons are small, silver has a tendency to form complexes with covalent bonds and to exhibit other properties such as catalytic activity typical of transition metals.

The atomic radius of silver (with 12-fold metallic coordination) is 0.144 nm; the ionic radius of Ag^+ (six-coordinate) is 0.137 nm, and of Ag^{3+} (six-coordinate) 0.075 nm.

2.2. Physical Properties

The physical properties of silver are generally intermediate between those of copper and gold. These three elements have strong similarities, although silver has some anomalous properties, which are directly related to the $d^{10}s^1$ electronic configuration and the irregularity of the atomic radii. Some physical data are given below:

Lattice constant at 20 °C	0.4086 nm
Atomic radius (in metal)	0.1445 nm
Melting point	961.9 °C
Boiling point	2212 °C
Specific heat capacity at 25 °C	0.23 J kg^{-1} K^{-1}
Thermal conductivity	418 W m^{-1} K^{-1}
Vapor pressure at	
1030 °C	1.33 Pa
1190 °C	13.3 Pa
1360 °C	133 Pa
1580 °C	1330 Pa
1870 °C	13 300 Pa
Density at 20 °C	10.49 g/cm^3
Density of liquid at *mp*	9.35 g/cm^3
Density of liquid at 1250 °C	9.05 g/cm^3
Brinell hardness	26
Modulus of elasticity	82 000 MPa
Tensile strength	140 MPa
Resistivity at 0 °C	1.465 Ωcm

Like copper and gold, silver crystallizes in a face-centered cubic structure in which each metal atom is surrounded by 12 neighbors. This high degree of symmetry results in a structure with many slip planes and is the reason for its good mechanical formability. Silver is only slightly less ductile than gold. It can be given a high polish and has a warm, white luster. Very thin films are blue or green by transmitted light, thicker films being yellow to brown.

Silver has the highest electrical conductivity, the highest thermal conductivity, and the lowest electrical contact resistance of all metals.

2.3. Chemical Properties

Molten silver absorbs oxygen and releases it during solidification, with bubbling of the metal surface. At 1000 °C, 1 cm^3 of molten silver dissolves a maximum of ca. 20 cm^3 of oxygen, corresponding to a stoichiometric composition of $AgO_{0.01}$. The solubility of oxygen in silver just below its melting point is only ca. 1/40 of that at 1000 °C. Hydrogen is very slightly soluble in molten silver, whereas nitrogen, carbon monoxide, carbon dioxide, and the noble gases are insoluble.

Halogens react violently with silver at red heat. Moist chlorine gas corrodes silver even at low temperature. Ozone blackens the surface of silver due to oxide formation.

Hydrogen sulfide (gaseous or in solution) and aqueous solutions of sulfides immediately form a black coating of silver sulfide on the surface of the metal. At high temperature, the reaction with hydrogen sulfide gas or sodium polysulfide solution can lead to complete conversion of silver to silver sulfide.

The solubility of metallic silver in water is very low, but it is sufficient to exhibit an oligodynamic (bactericidal) effect (see Section 13.2).

The preferred medium for dissolution of silver is hot, concentrated nitric acid (see Fig. 2):

$$3\,Ag + 4\,HNO_3 \longrightarrow 3\,AgNO_3 + 2\,H_2O + NO_3$$

Figure 2. Rate of dissolution of silver in nitric acid and sulfuric acid as a function of concentration and temperature

Silver also dissolves rapidly in hot concentrated sulfuric acid (Fig. 2):

$$2\,Ag + 3\,H_2SO_4 \longrightarrow 2\,AgHSO_4 + SO_2 + 2\,H_2O$$

Rates of dissolution in dilute sulfuric acid are appreciable if oxygen or hydrogen peroxide are present. The initially vigorous reaction with aqua regia

$$2\,Ag + 3\,HCl + HNO_3 \longrightarrow 2\,AgCl + 2\,H_2O + NOCl$$

is rapidly slowed by the formation of a coating of silver chloride. Most common oxidizing aqueous media attack silver, including chromic acid, permanganate solutions, persulfuric acid, selenic acid, and aqueous solutions of free halogens. The following also attack silver: hydrochloric acid, phosphoric acid, bromine water, solutions of alkali-metal chlorides, copper chloride, and iron chloride. The reactions are often strongly dependent on temperature and in some cases on the formation of protective coatings. Silver is resistant to aqueous solutions of organic acids and aqueous alkali.

Silver is fairly resistant toward fused sodium hydroxide at ca. 550 °C in the absence of atmospheric oxygen and moisture. Potassium hydroxide is more aggressive. Silver is attacked by fused salts such as sodium peroxide, potassium nitrate, sodium carbonate, potassium hydrogensulfate, and potassium cyanide.

3. Occurrence and Raw Materials

[1–3, 19, 26–29]

3.1. Formation, Abundance, and Distribution of Ores

Because of its chalcophilic character, silver became concentrated in oxidic sulfidic materials during the formation of the Earth's mantle, which has a silver content of ca. 10 ppm. The metallic core of the Earth should have a much lower silver content because silver does not alloy with iron or nickel. This is confirmed by investigation of iron meteorites. In the region accessible to mining (i.e., to a depth of 5 km), the Earth's crust has an average silver content of 0.05 – 0.1 ppm. Thus, silver is 100 to 1000 times more abundant than gold or platinum. The average silver content of the oceans is ca. 0.001 ppm [30], but it often reaches much higher values at the mouths of rivers. This enormous reserve of silver (10^9 t) cannot, however, be extracted economically.

Silver became concentrated at particular sites in the Earth's crust by the recrystallization of silicate magmas caused by volcanic action in impregnation zones. Most sulfidic, arsenidic, and antimonidic formations were originated in this way. Hydrothermal processes caused conversion to metallic deposits. Also, the action of the atmosphere and hydrosphere was involved (e.g., in the formation of caps over magmatic deposits). Unlike gold and the platinum metals, silver has not formed sedimentary deposits to any extent, since it is dissolved much more readily than gold or platinum by the action of the hydrosphere. However, silver-containing sedimentary deposits of other elements are known (e.g., Mansfeld copper slate).

3.2. Silver Minerals [3]

Nearly all silver minerals are compounds of silver with sulfur, its homologues selenium and tellurium, and their neighbors in the periodic table, arsenic, antimony, and bismuth. These ores generally have a metallic luster and are semiconductors. Other silver minerals include the halides and the free metal. The major mineralogical groups – oxides, silicates, spinels, phosphates, gypsum, and carbonates – are not represented.

Native silver occurs in the form of nuggets, dendrites, sand-like material, or sometimes as large lumps or blocks. It often forms mixed crystals with gold, and can also contain copper and other metals and metalloids.

Argentite, Ag_2S, is the most common silver compound found in the sulfidic ores of other metals, especially galena, PbS, in which it is present with other sulfidic minerals in the form of very fine inclusions. In the Middle Ages, argentite was often found in high concentrations and was a mineral in its own right with a high silver content.

Pyrargyrite, antimony silver blende, Ag_3SbS_3, is an important mineral occurring in true silver ores, which are now found and mined mainly in Central America.

Proustite, arsenic silver ore, Ag_3AsS_3, is of similar occurrence to the corresponding antimony-containing sulfur compound Ag_3SbS_3.

Stephanite, Ag_5SbS_4, is very characteristic of the silver ores familiar to miners from early times.

Cerargyrite, horn silver, AgCl, does not occur in large quantities. It has extremely low hardness and crystallizes with the NaCl lattice type.

Apart from the compounds mentioned above, many other well-defined silver minerals exist. Some of them, particularly the sulfur compounds, still make a significant contribution to silver production.

Some examples are given below:

Miargyrite	$AgSbS_2$
Polybasite (Eugenite)	Ag_9SbS_6
Freibergite	$(Cu, Ag)_{12}Sb_4S_{13}$
Freieslebenite	$Ag_3Pb_2Sb_3S_8$
Andorite	$AgPbSb_3S_6$
Stromeyerite	$Ag_2Cu_2S_2$
Schapbachite	$AgBiS_2$
Argyrodite	Ag_8GeS_6
Sternbergite	$AgFe_2S_3$
Argentopyrite	$AgFe_3S_5$
Argyropyrite	$Ag_2Fe_7S_{11}$
Sundite	$AgFeSbS_9$
Hessite	Ag_2Te
Petzite	Ag_3AuTe_2
Silvanite	$AgAuTe_4$
Bromyrite (Bromargyrite)	AgBr
Embolite	Ag(Cl, Br)
Iodite (Iodargyrite)	AgI

Silver is a component of most sulfidic minerals, at least at the parts-per-million level. The silver compounds are present as mixed crystals or as microscopic inclusions with a crystal structure that deviates from that of the matrix.

3.3. Deposits [3, 31–36]

The known silver deposits are associated mainly with vulcanism in the Tertiary period running, for example, in a continuous line along the entire west coast of the American continent (Fig. 3).

True silver ores, in which silver is practically the only valuable metal, are mined mainly in Mexico (Pachuca, Frenillo, and San Fernando de l'Oro) and to a small extent in the United States (Utah). In Europe, such deposits are almost completely exhausted. Worldwide, they still account for more than one-tenth of the silver mined. Depending on the price of silver, it can be economic to process materials containing 0.01 % (100 ppm) silver, or even less. The deposits in Ontario, which contain native silver associated with cobalt sulfide and arsenide, can also be regarded as true silver ores, since only the silver is extracted.

Argentiferous lead and lead – zinc ores, which often occur in association, are distributed widely. In almost all silver-producing countries, they constitute an important fraction of the silver produced by mining and account for ca. 50 % of world silver production. The separation and recovery of silver during lead production is profitable even for a silver content of a few parts per million. The important reserves in Europe include those in Spain (Lineares, Sierra Morena), Germany (Rammelsberg/Harz), Yugoslavia (Trepca), and to a lesser extent Italy (Montevecchio, Monteponi), Greece (Laurion), and France (Savoy). Argentiferous lead and lead – zinc ores are mined in large quantities in the United States (Helen, Montana; Denver, Colorado; Coeur d'Alene, Idaho), Mexico, Peru, Bolivia, and Argentina. In Australia and Tasmania, lead and lead – zinc ores are the primary source of silver. In North Africa (Djebel Hallouf, Tunisia; Beni-Sat, Algeria), Nigeria, and Namibia (Otavi), these are of some importance. In the Republic of South Africa, other silver ores are more important. In India, the extraction of silver from lead and lead – zinc ores is extremely important, and this appears to also be true of the Commonwealth of Independent States (CIS).

Argentiferous copper ores, which sometimes also contain nickel and cobalt, satisfy ca. 30 % of the world silver demand. Even very low contents of silver can be recovered profitably from copper ores, since almost all the copper is electrorefined, and the silver remains in the anode slimes. In Europe, the largest reserves of argentiferous copper ore are in Poland (Katowice), Yugoslavia (Bor), and Sweden. Smaller reserves can be found in Finland. The CIS, from which little information is available, is also believed to have reserves of this type. The largest argentiferous copper reserves in the world are in Canada (Sudbury, Ontario, Rouyn-Noranda, Quebec). Silver is also recovered during copper smelting in Chile, Bolivia, Peru, Katanga, Namibia, Zimbabwe, and the Republic of South Africa.

Figure 3. Reserves of silver by region

Extraction of silver from gold ores is carried out mainly in the Republic of South Africa, and also in Canada, Alaska, and Sweden (Boliden). The quantity obtained in this way is <10 % of world silver production. Silver-containing tin deposits are concentrated in Bolivia (Cerro de Pasco, Potosi) but also occur in Burma and Argentina. Silver produced from tin ores amounts to only 2 % of world production.

3.4. Secondary Silver [37–42]

The demand for silver that cannot be met by mining must be made up by recycling and by release from stocks (see Section 1.4). However, stocks of silver are often in a condition (e.g., type of alloy or low purity) that is not accepted directly by the market. Hence, these materials must generally be refined.

Silver coins have been almost entirely withdrawn from circulation. Some were refined immediately, but a smaller number were saved. From time to time, large stocks of these coins are released unpredictably, usually in association with speculative dealings on the silver market.

Even when the coins are of uniform composition, the alloy generally cannot be reused directly because, for example, the quantity is too large or the alloy is too complex. The silver content of coinage alloys is 40 – 90 %. Copper is the other main alloy component, and nickel, zinc, or traces of other metals are generally present.

The old Indian silver reserves come onto the market in the form of fittings and similar articles; the silver content is 90 – 95 %.

Photographic slimes, produced during the manufacture of films and photographic paper, have a silver content of 5 – 30 %. The silver is present as a halide, the remainder being mainly gelatin and water.

Approximately 50 % of the silver used in the photographic industry ends up in fixing baths. The silver-containing fixing bath solutions are rarely supplied directly to refineries. Instead, silver is usually extracted from them where they were produced, either by electrolysis to yield compact crude silver of fairly high purity (see Section 5.5) or by chemical reduction to give slime concentrates (10 – 60 % Ag).

The archives of X-ray films and motion pictures, which are stored for a limited period only, are a continuing source of recycled silver. In developed X-ray film the silver content is 1 – 2 %; in developed black-and-white film it is 0.2 %, but in developed color film the amount is negli-

gible. The films are converted to ashes or slimes with silver contents up to 90 %.

Offcuts of X-ray and graphic film from the photographic industry and film material stored too long (e.g., from military stocks) have a silver content up to 3 %.

Photographic printing paper offcuts from the photographic industry have a silver content of ca. 0.4 %. These papers used to contain up to 50 % barium sulfate filler, but modern papers are mainly polymer coated and have a low filler content.

Scrap silver from tableware and ornaments usually with silver content of 80 or 92.5 %, is important during periods of high silver prices. The treatment of silver-plated utensils (e.g., cutlery with ca. 4 – 5 % Ag) is usually profitable only in large quantities.

The electrical industry and its suppliers generate waste materials during the manufacture of electrical contacts at various stages of the production processes. Waste also arises from the production of small batteries for domestic electronic use and larger units for the military and air transport areas [43]. These cells often contain mercury. Silver-plated switching elements are produced in the electronics industry.

The chemical industry provides spent silver-containing catalysts [38]. These include silver wire mesh or silver crystals used in the oxidation of methanol to formaldehyde and Ag – α-Al_2O_3 catalysts for the oxidation of ethylene to ethylene oxide.

A regular, though small, quantity of silver comes from equipment and silver-plated vessels or pipework used in the chemical industry. Finally, the amount of silver waste from the production of dental amalgams is not inconsiderable. It consists of granules of Ag – Sn – Hg alloys and is usually contaminated with other materials, including organic substances.

3.5. Resources and Reserves [15, 24, 26, 36]

Mineral "resources" include all the principal known deposits, including those that have not yet been proved, but are only assumed. They also include deposits that are known for certain to exist, but cannot be extracted for economic or ecological reasons [44].

Mineral "reserves" include only those deposits that are already economically exploitable, or whose existence, based on prospecting work, is certain or probable [44]. These mineral reserves amount to ca. 250 000 t of silver at the present time. With a demand of ca. 10 000 t/a, silver is one of those metals whose known raw material reserves can supply the demand only for a limited period. By far the largest proportion of the silver is contained in lead, zinc, and copper ores, so silver production is linked primarily to the demand for these metals. This is probably not a good situation from viewpoint of future supplies. However, the advantage is that silver reserves are much more widely distributed than those of gold and the platinum metals, so the supply of silver to industrialized nations would be much less threatened by possible political crises than the supplies of other important raw materials.

4. Extraction from Ores [1, 3, 12, 19, 20, 44–46]

4.1. Extraction from Silver Ores

4.1.1. Smelting

In the early days, considerable quantities of silver were extracted simply by smelting high-percentage silver ores under oxidizing or reducing conditions with conversion of accompanying materials into slag. The starting materials were almost exclusively ores containing elemental silver, silver sulfide, or silver halides.

4.1.2. Amalgamation

For many centuries, amalgamation was the most important process for the treatment of true silver ores. Today, it is rarely used because of high costs, poor yields, and the toxicity of mercury. It is now carried on in privately owned small mines. The amalgamation process can be used directly only if the silver is native or is present as the chloride. In this form it will amalgamate on contact with mercury without any other treatment.

Amalgam formation does not take place as rapidly as with gold, but the reaction velocity

and rate of dissolution of silver in mercury are nevertheless fairly high. The copper-plate amalgamation process used with gold cannot be used with silver because reaction times are too short to give a useful yield. To ensure problem-free amalgam formation, the silver or silver halide particles should first be liberated, preferably by wet grinding. However, an extremely fine particle size is detrimental to the process.

Sulfidic, arsenidic, and antimonidic silver minerals do not react directly to form an amalgam and therefore require pretreatment. This can consist of a simple oxidative roasting process or roasting accompanied by chloridization or sulfation.

The reaction is accelerated and the yield improved by the addition of base metals (e.g., iron and copper), sodium chloride, copper (I) or copper (II) chloride, or copper sulfate. The following are some of the reactions that occur:

$$CuSO_4 + 2\,NaCl \longrightarrow Na_2SO_4 + CuCl_2$$

$$Ag_2S + CuCl_2 \longrightarrow 2\,AgCl + CuS$$

$$2\,Ag_3AsS_3 + 3\,CuCl_2 \longrightarrow 6\,AgCl + 3\,CuS + As_2S_3$$

$$CuCl_2 + Cu \longrightarrow 2\,CuCl$$

$$2\,Ag_3AsS_3 + 6\,CuCl \longrightarrow 6\,AgCl + 3\,CuS + 3\,Cu + As_2S_3$$

$$AgCl + Cu + Hg \longrightarrow CuCl + AgHg$$

The operating techniques and the choice of reaction conditions have undergone many changes. In the Patio process, a paste of finely ground ore, sodium chloride, mercury, and water was kneaded. Other processes employ copper or iron pans, stirring apparatus, or rotating vessels, either with or without heating. The resulting metallic phase is washed to remove accompanying materials, and the residual liquid mercury is separated from the solid amalgam. The latter is heated in retorts to distill off the mercury and yield impure silver. The overall yields of silver obtained in the amalgamation process reach 95 % under favorable circumstances. The loss of mercury amounts to 0.2 – 2 kg for each kilogram of silver.

4.1.3. Cyanidation

Because of its favorable economics, the aqueous cyanide process is the dominant process for extraction of silver from true silver ores. The conditions are essentially the same as those for the gold cyanide process (see → Gold, Gold Alloys, and Gold Compounds, Chap. 4.3.1.).

The ore is crushed, wet milled, and treated with an aqueous solution of sodium cyanide (5 – 10 g NaCN/L) for several days in a Pachuca tank [3]. Solids are removed by a thickener and filter, and silver is precipitated from solution by cementation on zinc dust. Other possible methods of recovering silver are ion exchange or electrolytic reduction [4]. Another process involves adsorption of the silver cyanide complex onto active carbon [47, 48], analogous to the carbon-in-pulp process for gold (→ Gold, Gold Alloys, and Gold Compounds, Chap. 4.3.2.). This process has been fully developed, but has not achieved the same importance or productivity as in the case of gold.

Silver chloride, either naturally occurring or produced by a chloridizing roast, is dissolved according to the equation

$$AgCl + 2\,NaCN \longrightarrow Na[Ag(CN)_2] + NaCl$$

Elemental silver is dissolved by passing air into the solution:

$$4\,Ag + 8\,NaCN + O_2 + 2\,H_2O \longrightarrow 4\,Na[Ag(CN)_2] + 4\,NaOH$$

Silver sulfide is also attacked, but more slowly, according to the following equations:

$$2\,Ag_2S + 8\,NaCN + 2\,O_2 + H_2O \longrightarrow 4\,Na[Ag(CN)_2] + Na_2S_2O_3 + 2\,NaOH$$

and

$$2\,Ag_2S + 10\,NaCN + O_2 + 2\,H_2O \longrightarrow 4\,Na[Ag(CN)_2] + 2\,NaSCN + 4\,NaOH$$

If the ores contain cyanide-insoluble silver compounds such as proustite (Ag_3AsS_3) and pyrargite (Ag_3SbS_3), cyanide extraction must be preceded by chloridization roasting. The dissolution of selenidic and telluridic compounds of silver by cyanide is also difficult, but is improved by fine grinding and roasting, as well as by the use of cyanogen bromide, which also increases the solvent action of the sodium cyanide on metallic silver:

$$2\,Ag + BrCN + 3\,NaCN \longrightarrow 2\,Na[Ag(CN)_2] + NaBr$$

Coarse metallic silver particles and manganese-containing silver ores can also lead to complications.

In general, the leaching of silver ores proceeds more slowly than with gold ores. Also, the yield with gold is higher than that with silver. If only metallic silver and silver chloride are present the yield can reach 98 %, but with other ores it is sometimes only 80 %. The final silver content of the powdered ore after the extraction of silver can be as low as 0.5 ppm in favorable cases.

4.1.4. Thiosulfate Leaching (Patera Process)

The process of leaching silver ores with thiosulfate solution was developed originally in Europe under the name of the Patera process. In the 1800s its importance increased in Central and South America, and later in North America as well. It replaced the amalgamation process, mainly because of its higher yield and lower cost. However, in a few decades it was replaced by the more economical cyanide leaching process and is now seldom used. Halide-containing silver ores or chloridized roasted ores undergo the same reactions that form the basis of the photographic fixing:

$$AgCl + 2\,Na_2S_2O_3 \longrightarrow Na_3[Ag(S_2O_3)_2] + NaCl$$

and

$$AgCl + 3\,Na_2S_2O_3 \longrightarrow Na_5[Ag(S_2O_3)_3] + NaCl$$

An excess of sodium thiosulfate should be present to prevent formation of the sparingly soluble complex $Na[Ag(S_2O_3)]$. The sodium thiosulfate concentration is usually 2.5 – 25 g/L. In variations of the process, sodium copper thiosulfate or calcium thiosulfate is used. Silver is precipitated from solutions by the addition of sodium sulfide. Yields of silver in the thiosulfate process are lower than in the cyanide process. Processing techniques are similar. A disadvantage of the thiosulfate process is that gold is insoluble and therefore not recovered.

4.1.5. Metallurgical Processes

True silver ores are often added directly to copper or lead smelting operations. This is especially true if the accompanying gangue minerals are of use in the smelting process (e.g., quartz, which benefits the copper shaft furnace process).

4.2. Extraction from Lead and Lead – Zinc Ores [34]

4.2.1. Production of Lead Bullion

In all process stages in the extraction of lead from lead and lead – zinc ores, silver follows lead. This applies to ore flotation; ore sintering; reductive smelting in the blast furnace (see → Lead, Chap. 4.); removal of copper by sulfur (see → Lead, Chap. 5.1.1.); and removal of arsenic, antimony,and tin by selective oxidation (see → Lead, Chap. 5.1.2.).

The next stage is the extraction of silver and other noble metals. Historically, several processes have been used in succession, each one replacing its predecessor, namely, cupellation (oxidation), cupellation after the silver has been concentrated by the Pattinson process, and concentration by the Parkes process followed by zinc removal and cupellation.

4.2.2. Cupellation without Prior Silver Enrichment

Before processes for concentrating the silver in lead bullion were developed (i.e., up to the 1800s), all the lead had to be converted to litharge (PbO) by oxidation (cupellation), and then the litharge removed from the silver-enriched metallic phase. This yielded an impure product that was converted to contemporary commercial-grade silver by a refining operation, which consisted essentially of further oxidation in a small furnace. Here, the elements copper, selenium, and tellurium were removed by repeated addition of pure lead, and subsequent addition of silver sulfate removed bismuth and lead. Oxidizing agents such as sodium nitrate and sodium carbonate were also added, and removal of the last traces of litharge formed was assisted by the addition of fluxes (e.g., glass).

4.2.3. Silver Enrichment by the Pattinson Process

A significant technical advance in the process of silver concentration was achieved by PATTINSON (1833). After this discovery, silver-containing lead no longer had to be treated by the costly cupellation process because the crude lead could be separated into two fractions, one with a low silver content and the other containing 2 % Ag. The process was based on the fact that when molten silver-containing lead is cooled (e.g., 0.2 % silver), pure lead separates until the silver content in the liquid phase reaches 2.5 % (see phase diagram for Ag – Pb in Fig. 27). However, because of the difficulty of separating lead crystals from the silver-containing molten metal, complete separation cannot be achieved in a single operation. If the process is repeated, a grade of lead with a low silver and bismuth content ($\leq$10 ppm silver), and a grade of lead with a high silver content ($\leq$2 % silver) that is suitable for cupellation, can be produced, at an acceptable cost.

The fraction that contains silver and bismuth also contains gold. The theoretical silver content of 2.5 % is not achieved in practice, since the small temperature difference between the melting point of pure lead (327 °C) and that of the eutectic mixture (304 °C) means that separation becomes more difficult as the eutectic point is approached. The presence of copper, nickel, arsenic, antimony, and bismuth can also interfere with the removal of silver. Larger amounts of these elements therefore have to be removed first. Some copper goes into the Pb – Ag alloy, and some into the lead crystals, so that purified lead from the Pattinson process always contains some copper. Arsenic is found mainly in the lead crystals, whereas nickel and antimony follow bismuth into the silver-containing melt. In the usual operating procedure, either the lead crystals were removed by hand sieving, or the silver-containing melt was siphoned or tapped off. The fractions obtained were then treated again by crystallization. A series of cast iron vessels of 10 – 15 t capacity was employed, using countercurrent flow from the center to both sides. About 15 units were needed. Two-thirds of the contents of the vessel were recovered as crystals, and one-third remained as melt.

4.2.4. Silver Enrichment by the Parkes Process

The silver in bullion lead, together with gold and platinum metals, is concentrated by the Parkes process (→ Lead, Chap. 5.1.3.). The process involves the production of a solid alloy of lead, zinc, and silver by stirring zinc into molten impure lead. This so-called zinc crust floats on the surface of the molten metal (450 °C). It is skimmed off, the adhering liquid lead is removed by hot pressing, and the zinc is distilled in a retort or vacuum furnace. The residue consists of a lead – noble-metal alloy with up to 50 % silver, ca. 1 % zinc, and some copper, arsenic, antimony, and bismuth. It is oxidized by cupellation to obtain crude silver or, if appreciable amounts of gold are present,auriferous silver.

4.2.5. Cupellation of Enriched Lead

The cupellation process removes lead and small amounts of other base elements from the silver and accompanying noble metals by selective oxidation.

In the cupellation process, the lead melt is blown with air to produce molten lead oxide (litharge, PbO), while the silver, gold, and platinum-group metals do not react. The liquid layer of lead oxide produced covers the molten metal completely, but the oxidation reaction is not seriously impeded since the hot litharge takes up oxygen and then releases it to the molten metal. Copper, which is usually present, also assists the transport of oxygen. During cupellation, the temperature must be sufficiently high for the litharge (*mp* 886 °C) to form a low-viscosity melt that does not incorporate metallic and noble-metal components. At the end of the process, when the melt has a higher silver content and therefore a higher melting point, the operating temperature must be significantly greater than the melting point of silver (963 °C). In practice, the process is operated at 900 – 1100 °C. If the temperature is too high, volatilization can occur, which leads to losses of silver. The molten litharge formed must be removed continuously to prevent the layer from becoming too thick. The end of the smelting process is recognized when the litharge layer becomes thin and finally

breaks up. The bright surface of the silver can then be seen. The last traces of litharge are mixed with marl (calcium carbonate) to facilitate its complete removal. Molten silver is usually cast into anodes for electrorefining. The copper and lead contents of the crude silver should preferably not exceed 1.0 and 0.1 %, respectively. Of the normal impurities, zinc, arsenic, antimony, and copper go mainly into the litharge that is first produced, although some go into the slag that can be removed after the initial melting operation. Bismuth becomes concentrated in the end fraction of the litharge.

The so-called English cupellation furnace (cupel) is now nearly always used for the cupellation process in lead smelting plants. The hearth, which is replaceable, is lined with magnesite bricks, and can be tilted to pour off the litharge and molten silver. It is fired under a flat hood. Air is blown through nozzles over the surface of the melt, freeing part of the metal surface of molten litharge. The litharge layer is removed when it reaches a thickness of ca. 1 cm. About 100 kg of lead is oxidized per hour per square meter of furnace area; the capacity is ca. 1000–2000 kg silver. The so-called German cupel is larger and has a fixed hearth with a launder at the front that can be lowered continuously, so that as the volume of molten metal decreases, the litharge is continually removed. Molten silver must be skimmed off. The greatest advantage of the smaller English smelting furnace is that less silver is required for its operation. The lining of the hearth of the cupel picks up a certain amount of silver, so that after dismantling, the broken lining with litharge attached must be treated in a lead shaft furnace.

4.2.6. Silver Extraction from Electrolytic Lead Refining

The aqueous electrorefining of lead bullion (see → Lead, Chap. 5.2.) usually produces anode slimes that are difficult to process, whose composition is similar to that of the anode slimes from the electrorefining of copper [Cox] (Table 3). They contain all the noble metals and other impurities associated with crude lead. They are treated by pyrometallurgical processes to obtain auriferous silver and other valuable metals. Copper anode slimes and lead anode slimes are sometimes mixed and treated together.

4.3. Extraction from Copper and Copper–Nickel Ores [33,47–53]

4.3.1. Formation of Silver-Containing Copper Anode Slimes

In silver-bearing ores of copper, copper–nickel, and copper–nickel–cobalt, the silver stays with the copper-rich fractions during all concentration stages, including mechanical processing and smelting (see → Copper, → Nickel). It is transferred from the copper matte into the crude copper. Gold also follows the copper and silver, but only a small fraction of the platinum metals go to the crude copper, the majority accompanying the nickel. Today, all crude copper is electrorefined. The copper anode slimes formed contain almost all the silver and noble metals, and large amounts of copper, lead, nickel, selenium, tellurium, arsenic, antimony, and sulfur. Because of their composition, the economic and ecologically acceptable treatment of copper anode slimes is one of the most difficult tasks in the metallurgy of noble metals. Before the introduction of electrorefining, silver had to be extracted from copper matte produced by the copper shaft furnace (see Section 4.3.4).

4.3.2. Pretreatment of Copper Anode Slimes

Coarse copper particles that become detached from the anodes or appear as growths on the cathodes are removed first by sieving which eliminates ca. 30 % of the weight of the slime. In the following pretreatment process, elemental copper (formed by disproportionation of Cu^+ in the electrolyte), copper telluride, and copper selenide are dissolved by treatment with 4–5 mol/L sulfuric acid, with addition of air or oxygen at 60–95 °C. The effectiveness of this technique is limited, especially if the selenium content is high.

Examples of the composition of untreated and pretreated copper anode slimes are given in Table 2. The wide variation in the compositions

Table 2. Typical compositions [%] of untreated and pretreated copper anode slimes and untreated lead anode slime

of the slimes both before and after treatment results in many process steps being carried out under very specific conditions that the processing industries often do not disclose.

4.3.3. Processing of Copper Anode Slimes [54,55]

Processing of Copper Anode Slimes by Roasting.

Oxidizing Roasting at 300–400 °C. Roasting is performed on a thin layer of material or in an air-blown rotary furnace. Metallic copper is oxidized fairly easily. The selenides and tellurides of copper and silver are converted to selenites and tellurites. Only a small fraction of selenium dioxide is volatilized. The product is treated with dilute sodium hydroxide solution, which dissolves mainly the selenium. Treatment with dilute sulfuric acid dissolves tellurium preferentially, and some silver as well. Most of the selenium and tellurium (75–90 %) can be brought into solution.

Oxidizing Roasting at 600–800 °C. The material is mixed with bentonite as a binder and with copper(II) oxide and iron(III) oxide as reaction accelerators, pelletized, and reacted with air blowing. Up to 98 % of the selenium can be recovered as SeO_2 sublimate. The product is then leached with dilute sulfuric acid, which dissolves copper, tellurium, and some silver.

Roasting with Sodium Carbonate. A mixture of anode slime with sodium carbonate (sometimes with the addition of sodium hydroxide or sodium nitrate) is generally pelletized and heated at ca. 400 °C in air, so that selenium and tellurium are converted into water-soluble compounds. Copper, which is also oxidized, and most of the tellurium can be dissolved with dilute sulfuric acid. The resulting solution also contains some silver in the form of its sulfate.

Processing of Copper Anode Slimes by Sulfation. Dried anode slime is mixed with concentrated sulfuric acid and heated, first to 300 °C, and then to 400–500 °C, causing sulfation and oxidation. Most of the selenium sublimes as selenium dioxide. Most of the copper, silver, and nickel can be dissolved with hot water, whereas the tellurium oxide formed remains undissolved in the residue.

Hydrometallurgical Treatment of Copper Anode Slimes [56]. Copper anode slimes can be dissolved in oxidizing acids. Treatment with $HCl-Cl_2$ [57] gives a residue that contains silver chloride, silica, and lead chloride. Gold, plat-

inum, selenium, and tellurium must be recovered from solution, and other accompanying elements are eliminated by wastewater treatment.

Copper anode slime is reportedly digested in a high-pressure process, either after the removal of copper or after one of the roasting processes [58]. Temperatures between 160 and 180 °C are recommended. If 10 – 40 % sodium hydroxide solution is used, selenium and tellurium go into solution, while silver and most of the copper remain undissolved. If dilute sulfuric acid is used in the presence of air, selenium, tellurium, silver, and copper dissolve. Problems arise if selenium and tellurium exceed an oxidation state of 4. Solutions of selenate(VI) and tellurate(VI) cannot be readily reduced to the elements. The favorable economics of the pressure process are mainly a consequence of the improved sharpness of separation compared to other processes and of the short reaction times.

Processing of Copper Anode Slimes in a Cupellation Furnace. If pretreated anode slimes contain only moderate amounts of copper, selenium, tellurium, antimony, and arsenic, the noble metals can be recovered in a cupellation process. However, a two-stage process in separate furnaces is necessary for treating the low-grade and high-grade materials.

Processing of Copper Anode Slimes in the Doré Furnace. In the Doré process, pretreated anode slimes (i.e., with copper removed) are treated with slag-forming and oxidizing materials for a long period in the molten state. In addition to the crude silver fraction, three types of slag are usually produced and removed separately. Flue dust is also obtained.

Sodium carbonate, lime, cullet (broken glass), and sand are added to form a silicate slag that takes up primarily iron, arsenic, antimony, lead, nickel, and tin. Selenium matte, which consists mainly of selenides and tellurides of copper and silver, forms an intermediate layer between the silicate slag and the molten metal if the starting material has a high selenium and tellurium content. After removal of the silicate layer, selenium matte is blown with air and treated with sodium carbonate and sodium nitrate. This produces a slag that contains sodium selenite, sodium selenate, sodium tellurite, sodium tellurate, and only ca. 1 % silver. This slag is tapped off, and the molten metal is reacted with additional sodium nitrate to remove the remaining copper, lead, selenium, and tellurium. The doré silver produced has a noble-metal content of 99.0 –99.5 % and is sent to the silver electrorefining process. Its main impurity is copper, but it also contains some lead, bismuth, selenium, and (depending on the starting material) tellurium. Doré furnaces are usually oil fired along their length, and are similar to German fixed hearth or English tilting hearth cupels. For hearth sizes between 3 and 6 m^2, a charge of 8 – 15 t anode slime is treated in 100 – 200-kg lots. The reaction time is 3 – 6 d or longer. Waste gases are passed through dedusting chambers, coolers, scrubbers, and electrostatic gas purifying equipment.

Slags produced by oxidation of selenium matte, and flue dust and slimes from the scrubbers are major sources of selenium (→ Selenium and Selenium Compounds) and tellurium (→ Tellurium and Tellurium Compounds). The most valuable material in the wash liquor is selenium. All other drosses, including residues from selenium and tellurium production, which contain noble metals, are recycled to the copper shaft furnace or to the doré process.

Typical compositions of intermediate products are given in Table 3. These can, however, vary over a wide range.

Treatment of Copper Anode Slimes with Molten Salts. Powdered anode slimes can be digested below their melting point, without forming molten metal by fusing with Na_2CO_3 and $NaNO_3$ or similar mixtures. The reaction is also possible at sintering temperature. After leaching with water, a separation process must be used similar to that used after acidic hydrometallurgical digestion of copper anode slimes.

Other Methods of Processing Copper Anode Slimes. Dried, decopperized anode slimes can be treated with chlorine at ca. 700 °C. Silver chloride remains in the residue, and the chlorides of selenium, tellurium, copper, tin, arsenic, etc., are sublimed or distilled.

If the decopperized anode slimes are heated to 700 °C in a vacuum, silver selenide decomposes and selenium sublimes.

4.3.4. Silver Extraction from Copper Matte

Before electrolytic technology became available for refining copper, copper – silver separation had to be performed on copper matte from the copper shaft furnace. Two main processes were used.

In the Augustin process, copper matte was roasted under chloridizing conditions, and the silver chloride formed was leached out with hot brine, leaving behind the unchanged copper sulfide (Fig. 4).

In the mid-1800s, the Augustin process was replaced by the Ziervogel process, which involved sulfation roasting of powdered copper matte with a precisely controlled temperature program. This first decomposes silver sulfide to silver and sulfur. The silver reacts with sulfur trioxide liberated from iron sulfate and copper sulfate, forming the more stable silver sulfate, which is water soluble. The copper is then in the form of copper(II) oxide. Treatment with water acidified with a little sulfuric acid dissolves silver sulfate, leaving copper(II) oxide in the residue. More than 90 % of the silver goes into solution, 5 % is in the flue dust, and the rest stays in the copper oxide (see Table 3). Gold is undissolved and remains in the copper. Thus, the gold content of copper matte cannot be recovered by the Ziervogel process.

4.4. Extraction from Gold Ores

The silver present in most gold ores follows the gold in all pretreatment processes, as well as in the aqueous cyanide process. Crude gold as mined usually contains 10 – 12 % silver. In the commonly used Miller process, silver and base metals are separated from gold by conversion to their chlorides (AgCl, CuCl, etc.). The reaction is carried out by passing chlorine through the molten metal (see → Gold, Gold Alloys, and Gold Compounds, Chap. 5.2.). Silver chloride and the base-metal chlorides form a slay on the molten gold to which borax is added as a flux. Solidified slag is leached with a solution of sodium chlorate in hydrochloric acid, which dissolves the base-metal chlorides and leaves silver chloride as residue. The silver chloride is reduced with zinc dust in suspension to precipitate crude silver, which is then electrorefined (see Section 6.4).

Small amounts of silver and gold are also recovered from sodium carbonate-containing slag and broken crucible fragments from the melting of precipitated gold in the cyanidation process. These materials are treated by the lead – silver blast furnace process and the cupellation process (see Section 5.3).

4.5. Extraction from Tin Ores

Silver-containing concentrates from the treatment of Bolivian tin ores usually contain a few hundred parts per million of silver, present mainly as sulfidic compounds. The ore is roasted under oxidizing conditions in the presence of sodium chloride, to convert silver to silver chloride, which can then be leached out. Alternatively, the concentrates can be treated by an amalgamation process, with or without a preliminary roasting operation (see Section 4.1.2). A more economical solution is often to add these materials to the feed for the copper smelting process. Silver then ends up in anode slimes from the electrorefining of copper.

Leaching with Hydrochloric Acid or Aqueous Sodium Chloride. Leaching with HCl is carried out at ca. 100 °C. Tin dioxide is not dissolved, but most of the other materials are, including silver. Silver can be cemented with scrap iron. The cementate produced is treated in copper or lead smelting processes.

Leaching with Aqueous Thiosulfate. When the silver content is high, aqueous thiosulfate is often used because of the high and selective solubility of silver chloride in thiosulfate. The process was formerly used widely to treat true silver ores (see Section 4.1).

5. Recovery from Secondary Silver

[3, 20, 37–42, 56, 57]

The collection and treatment of silver-containing scrap and residues is of major economic importance. These materials can be separated into metallic products that can be melted to form a homogeneous material and nonmetallic concentrates (drosses, see Section 3.4). The amount of silver in this field corresponds to about 20 – 40 % of primary silver production. As in the production of silver from ores, the aim is to obtain a crude silver that can be treated in the refining process. Only seldom is good-delivery silver obtained that does not need refining.

5.1. Via Copper Smelters

In principle, all silver-containing recycled materials can be treated in the usual copper production processes (→ Copper ; see also Section 4.3). Since the silver is tied up in the process for a long period, only a few types of silver-containing scrap are treated in this way. Copper must be the principal base metal present. This category of scrap includes fabrication waste and recycled material from the electronics industry. Usually, they would be fed to the copper shaft furnace or the cupel. Flue dust and copper matte from the lead – silver blast furnace are also treated in copper smelters.

5.2. Via Lead Smelters

The only use of lead smelters in silver recycling is in treating the silver-containing flue dusts from lead – silver blast furnaces. These smelters are very suitable for dealing with the high lead and zinc content of flue dusts.

5.3. Via the Lead – Silver Smelting Process [23, 24, 58]

Some companies that recover noble metals from scrap use a special lead-based smelting process. The pyrometallurgical reactions are the same as those used for noble-metal extraction in ancient times and correspond in principle to those of the modern lead smelting process. There are two main stages of the process: the blast furnace stage and the oxidation stage. In the blast furnace, silver and the other noble metals are dissolved in the lead formed in the process. In the oxidation furnace (converter), the lead is then oxidized to lead oxide (PbO, litharge), which can be easily separated from the metal melt. The main product is a metal with a high percentage of silver (auriferous silver). Lead oxide is recycled by the blast furnace process. The accompanying elements that enter the system in the raw material are eliminated via three byproducts of the blast furnace: copper matte, slag, and flue dust. Slag, which contains the oxide and silicate components, is worthless and can be discarded. Copper matte, which contains the chalcophilic elements copper and nickel, and flue dust, which contains zinc and cadmium, must be treated separately.

Nonmetallic concentrates (drosses) containing noble metals are generally smelted in the lead – silver blast furnace. Metallic scrap materials are often treated directly in the converter. In this case, base metal oxides go into the litharge, though some are in the flue dust. The choice of treatment process is often determined by the cost of tying up the value of the noble metal, thereby incurring loss of interest, rather than by actual operating costs.

Typical compositions of materials involved in the lead – silver smelting process are given in Table 4.

The Blast Furnace. In the blast furnace (Fig. 5), the following reactions take place:

$$C + 1/2\,O_2 \longrightarrow CO$$

$$PbO + CO \longrightarrow Pb + CO_2$$

Here, lead is formed from the litharge produced in the converter and acts as a collector for noble metals. The chemical reactions, which also form the copper matte and slag phases, take place at 1100 – 1300 °C.

In the operation of the lead – silver blast furnace a large number of parameters must be controlled and various boundary conditions observed. The widely varying composition of the raw materials and of the recycled litharge, must be compensated by varying the amount of quartz, limestone, sulfur, iron oxide, pyrites, and coke added. This ensures the formation of a low-viscosity slag that does not incorporate droplets of metal. The amount of sulfur added is calculated from the amount of nonferrous metal. The ability of the slag to take up aluminum oxide is limited. If the Al_2O_3 content reaches 20 %, the slag viscosity increases. This must be taken into account when catalysts supported on γ- or α-aluminum oxide are processed.

The ability of lead and auriferous silver to alloy with gold, platinum, and palladium is unlimited. However, rhodium, iridium, ruthenium, and osmium, together with other refractory metals such as tungsten and molybdenum, collect at the bottom of the blast furnace or at the bottom of the converter. For this reason, as well as the volatility of ruthenium and osmium compounds in the blast furnace, the presence of these metals is undesirable. Halides in the raw materials end up almost completely in the flue dust in the form of lead and silver halides. Zinc and cadmium take the same route.

The elements arsenic, selenium, and tellurium are kept out of noble-metal smelters as much as possible because they form compounds with noble metals (speisses) that are difficult to process.

Instead of using a blast furnace, the lead smelting stage can be operated in a flame-fired furnace. This, too, is followed by an oxidation stage.

Oxidation in the Converter. The following reaction takes place in a converter:

$$Pb + 1/2\,O_2 \longrightarrow PbO$$

The molten lead oxide (litharge) produced is removed continuously from the surface of the liquid metal and recycled to the blast furnace. Silver and other noble metals remain in the elemental state and are concentrated from ca. 20 % in

Table 4. Typical compositions of materials produced during noble-metal smelting

Source	Material			Nonnoble impurities, %												Relative quantities, t

Figure 5. Silver recovery in a blast furnace and converter

the starting material (lead bullion) to ca. 99 % in auriferous silver (Table 4). The lead oxide contains silver particle inclusions, considerable quantities of copper, and small amounts of other accompanying base metals as their oxides (Table 4).

The oxidation of argentiferous lead was carried out for a long time exclusively in shallow flame-fired furnaces (cupels) like those used in the lead smelting process. Lead was oxidized by applying a flame and a stream of air to the surface of the melt. The reaction temperatures during cupellation were ca. 900 °C at the start and ca. 1100 °C at the end of the process. The lower limit is determined by the melting temperature of PbO (890 °C), silver (961 °C), and auriferous silver (ca. 1050 °C).

Since ca. 1975, rotary noble-metal converters have been used instead of cupels. The oxidizing agent is gaseous oxygen [59]. Such converters contain several tonnes of metal, and the litharge is poured off through a spout. A natural gas – oxygen burner produces very intense heating. The great economic advantages compared to

conventional cupellation hearths result from the much higher rate of reaction due to convection in the melt, low energy requirements, improved working conditions, longer lifetime of the furnace lining and the potential for automation.

If scrap alloys are processed directly in the converter and not in the shaft furnace, to speed up noble-metal throughput, the litharge picks up more base metal, mainly copper. The copper can be removed in copper matte only after the litharge has been transferred to the blast furnace. Therefore the noble metal is sometimes concentrated by a preliminary treatment of the raw material (see Sections 5.4 and 5.5).

Both the oxidation process with direct feeding of scrap metal and the shaft furnace process can be carried out with copper instead of silver. This is appropriate if the raw material has a high content of platinum-group metals that do not readily form alloys with silver (e.g., rhodium). The copper oxide formed is then usually processed by leaching with sulfuric acid.

5.4. Via Scrap Metal Leaching [60]

Alloys based on silver – copper, which can also contain nickel, zinc, other base metals, gold, and platinum-group metals, can be treated hydrometallurgically to recover the noble and base metals.

The basis for this is the very wide miscibility gap between silver and copper in the alloy system (see Fig. 15). Copper can be selectively dissolved by dilute sulfuric acid, with addition of air, gaseous oxygen, or hydrogen peroxide:

$$Cu + CuSO_4 \longrightarrow Cu_2SO_4$$

$$Cu_2SO_4 + H_2SO_4 + 1/2\,O_2 \longrightarrow 2\,CuSO_4 + H_2O$$

Copper can also be oxidized in a prior roasting stage. Dissolution by sulfuric acid is then possible without addition of oxidizing agents. The preferred reaction temperature is ca. 90 °C. In the concentration range Ag 30 Cu 70 to Ag 70 Cu 30, the silver in the alloy retains its structure during the process. The reaction rate decreases nonlinearly with increasing depth of attack due to the restriction of diffusion through the silver skeleton. For acceptable times of solution, the thickness of the alloy pieces should not exceed 0.1 – 0.2 mm. This can be achieved by machining the alloy to form chippings or by spraying the molten metal to form a powder. In both cases, a material is obtained that can easily be kept in suspension by stirring. If the solidified metal is slowly cooled to ca. 200 °C, formation of mixed crystals on the silver-rich side of the system can be inhibited (see Fig. 15), which decreases the rate of copper dissolution. The silver that remains is generally electrorefined. Copper sulfate or electrolytic copper can be recovered from solution.

Silver-containing alloys can be dissolved in nitric acid or hydrochloric acid – chlorine, and silver can be precipitated as silver chloride. However, this is not economical on an industrial scale. Copper nitrate can be converted to copper oxide or copper(I) chloride. Copper cementation is also useful if it is connected with a converter process.

5.5. Via Scrap Metal Electrolysis [61]

Dietzel Electrolysis (see Fig. 6) [62]. A recycled alloy, usually of silver, gold, and copper, is anodically dissolved in an electrolyte of slightly acidified copper nitrate. The anode and cathode spaces are separated by a textile diaphragm. The anolyte is removed continuously via an overflow, and silver is precipitated from it by cementation with copper. The desilvered anolyte is fed continuously into the cathode space, where copper is deposited on rotating roller-shaped cathodes and is removed in sheet form from time to time. The flow of desilvered solution into the cathode space, and the outflow of silver-containing solution from the anode space, which is caused hydrostatically, produce a flow of solution through the diaphragm in the direction of the anode. Very little dissolved silver reaches the cathode space. Copper with a low silver content is recovered at the cathode.

The process is still used industrially. One disadvantage is the high cost of equipment. Several variations of the process have been described [63].

Demag Electrolysis [63]. Copper can be dissolved from silver – copper anodes by a dilute sulfuric acid electrolyte and deposited on the cathode, while silver remains undissolved. If the

metal has an average silver content, as is necessary for the sulfuric acid leaching of scrap silver (see Section 5.4), a felt-like mass of silver is produced that retains the shape of the original anode. With increasing depth of penetration into the anode, the dissolution reaction is inhibited by the silver structure, which presents diffusion. Therefore, the thickness of the anode sheet must not exceed ca. 5 mm. If anode baskets are used, avoiding the production of zones from which the copper has not been completely removed is even more difficult.

Figure 6. Dietzel electrolysis (front view)
a) Roller-shaped cathodes; b) Diaphragm; c) Anode; d) Pieces of scrap silver; e) Anode slime

As dissolution proceeds, the current – voltage characteristic of the electrolytic cell changes. Potentiostatic control of electrolysis is therefore essential to prevent excessive voltage, which would cause silver to dissolve and be deposited with copper on the cathode. As in the sulfuric acid dissolution process, preliminary thermal treatment must be carried out to prevent excessive amounts of copper from appearing in the silver crystals due to the formation of silver – copper mixed crystals. Also, the copper-containing electrolyte must be carefully washed out of the silver felt, which contains very fine pores.

Electrolysis in sulfuric acid also removes the other metals that usually accompany copper and silver, but nickel accumulates in the electrolyte where it causes problems. If zinc, cadmium, lead, and tin are present in the recycled alloy, it should be oxidized first in a converter. Tin, especially, can interfere with electrolysis by precipitation of stannic acid.

5.6. Processing of Flue Dust

Flue dust from the waste gases of the lead – silver smelting process nearly always contains silver. Flue dust can be recovered quantitatively by means of settling chambers, electrostatic processes, wet and dry filtration, and scrubbing towers.

Dust from the lead – silver shaft furnace and the cupel generally contains the following: lead(II) oxide, lead sulfide, silver sulfide, elementary silver, copper oxide, copper sulfide, slag components, etc. It can normally be recycled to the shaft furnace.

If halides, mainly from photographic materials, are introduced into the smelting process, they are essentially bound as halides of lead and silver, which because of their low boiling points (*bp* of $PbCl_2$ = 916 °C), are found almost entirely in the flue dusts. If the flue dust is recycled to the shaft furnace the halides revolatilize, and only the other components are reduced. The halide content of flue dust increases due to the recirculating system, and when it exceeds a certain figure, the dust is treated with sodium carbonate solution or milk of lime. Soluble halides are disposed with wastewater. All heavy metals, nonferrous metals, and noble metals remain as oxides, carbonates, or metals in the residue, which is fed back to the shaft furnace process.

Like the halides, the elements zinc and cadmium become concentrated in the flue dust, passing unchanged through the reducing shaft furnace due to their vapor pressure if they have not already been removed in the slag during cupellation or by distillation from the feed material. After sufficient concentration, they are dissolved as sulfates by treatment with sulfuric acid. The main component of the residue, which is fed back to the shaft furnace, is lead sulfate. The distribution of silver between the solution and the residue must be monitored.

The arsenic, antimony, selenium, and tellurium in flue dusts are especially troublesome. Noble-metal smelters attempt to remove these elements, which are readily sublimable in the elemental state, before the flue dust is introduced into the recycling system. Recycling of dusts of this type is usually confined to copper and lead smelters, where the elements can be picked up in the slag, either in the shaft furnace or the doré furnace.

5.7. Processing of Copper Matte [64]

Because of its high silver content, copper mate (see also Section 4.3.4) from the lead – silver shaft furnace used in noble-metal smelting must be treated without delay to minimize interest losses. Silver can be recovered quickly by the lead shaft furnace process, followed by isolation of silver by the Parkes process (see Section 4.2.4). Treatment in the shaft furnace of a copper refinery is possible, but silver is bound for a long time in the copper electrorefining stage and then in the copper anode slimes. In principle, copper matte can be ground, roasted in air, and leached with dilute sulfuric acid to dissolve the copper and leave a silver-containing residue. The same result is obtained by directly leaching ground copper matte with dilute sulfuric acid at ca. 160 °C in autoclaves, with introduction of air. Direct electrolysis of copper matte anodes has also been proposed. Copper is deposited on the cathode, whereas silver remains in the anode slime. However, mechanically stable anodes are difficult to produce.

5.8. Processing of Photographic Materials [40,42,64]

Films. Film material (1 – 3 % Ag) in which the film base is nonuniform [usually poly(ethylene terephthalate), PET, or cellulose triacetate, CTA], and therefore difficult to reuse, is best treated by incineration, generally after size reduction in a cutting mill. The combustion temperature must be controlled carefully to minimize volatilization of the silver, which can lead to high losses in the combustion gases, and consequent high recycling costs. The durability of the furnace lining is also strongly dependent on temperature. Usual incineration temperatures are in the range of 1000 – 1200 °C. The temperature can be lowered by water spraying [65].

If pyrolysis [66] is used rather than incineration, flue dust problems are largely avoided. The end products of incineration and pyrolysis can be treated by smelting or electrorefining, depending on the silver content. In pyrolysis, temperatures of 600 – 700 °C are used. The silver content in the remaining ashes ranges from 15 to 35 %, depending on the process. Typical concentrations of silver in the flue dust are in the region of 20 %.

If the film substrate is to be reused, a washing process is employed that destroys the gelatin coating and liberates silver or silver halide. Most important for the washing process is the kind of film carrier material. Triacetate film, mainly applied in amateur photography, is relatively easy to process. PET material from graphic and X-ray applications is more critical because of the need for complete removal of the adhesion promoter. Suitable washing solutions include hot dilute sulfuric acid, hot dilute sodium hydroxide solution, sodium hypochlorite solution, or enzyme solutions [67]. If developed films are to be treated, the grains of silver can be oxidized with a solution of iron (III) chloride, into which air is injected continously for reoxidation of iron (II), and the silver halide formed can be washed off with a solution of sodium thiosulfate. The silver concentrates, which must be reduced to silver if silver halides are present, generally have a sufficiently high silver content to be treated by electrorefining.

Older films, such as those from archives, must be tested carefully to determine whether they are made of extremely flammable nitrocellulose film material. The storage of such materials requires elaborate safety precautions.

Photographic Paper. Washing processes are uneconomic because the silver content of photographic papers is low and the substrate materials cannot be reused after washing. Instead, silver is usually recovered by incineration or pyrolysis.

Photographic Emulsions. The photographic industry produces unusable, usually pasty or lumpy residues of photographic emulsions, which are supplied to recovery plants for treatment. Apart from silver halides, they contain water and considerable amounts of gelatin. Treatment can be by combustion, pyrolysis, or chemical breakdown of the gelatin in solution or suspension. The silver halides can be reduced at the same time or in a subsequent operation. The isolated silver halides can be converted into metallic silver by fusion with sodium carbonate or by hydrometallurgical reduction.

Fixing Baths [68–75]. Silver-containing fixing baths from photographic plants and laboratories, hospital X-ray departments, and doctors' surgeries are rarely sent directly to recovery

plants. They are generally treated chemically or electrochemically in situ to precipitate the silver. Alternatively, they may be purchased by specialist companies that convert then to concentrates and detoxify the highly contaminated wastewater.

In times of high silver prices, ca. 75 % of all fixing baths are treated to recover the silver in spite of their wide dispersal. In addition to the economic value of the silver recovered from fixing baths, ecological considerations are important.

In concentrations of $\geq$0.04 ppm, silver ions have harmful effects on biological systems. However, these effects are much reduced if the silver in photographic wastewater is in the form of a complex. The potentially harmful effects on biological wastewater treatment systems are prevented by rapid reaction of dissolved silver with the sulfide that is always present in such systems forming insoluble and, therefore nontoxic, silver sulfide. Although no harmful effects on biological sewage treatment plants have been observed in practice, the silver concentration in wastewater passing into the main drainage system is usually limited to 1 – 2 ppm.

Many processes have been used to treat silver-containing fixing baths. Chemical precipitation processes have largely been displaced by electrolytic processes for ecological reasons. The original method of precipitating silver sulfide from the fixing bath by adding sodium sulfide is obsolete and unacceptable for reasons of industrial hygiene. Precipitated silver sulfide was often reacted with iron powder above the melting point of silver to form metallic silver and iron sulfide. Later, silver was precipitated by adding trimercapto-*s*-triazine [73]. This reaction takes place without liberation of hydrogen sulfide and can be followed potentiometrically. The method is also suitable for treating the much more dilute fixing and bleaching baths from color photography, for rinsing solutions, and for wastewater that contains copper, cadmium, mercury, nickel, and lead. Final concentrations of ca. 1 mg/L silver are obtained. The cementation of silver with zinc powder is dangerous due to the hydrogen evolved and has led to severe accidents. It also produces zinc-containing wastewater. The use of sodium borohydride as reducing agent has been suggested, although this also results in evolution of hydrogen. The use of sodium dithionite as a reducing agent is recommended in the photographic industry:

$$2\,Na_3[Ag(S_2O_3)_2] + Na_2S_2O_4 + 4\,NaOH \longrightarrow 2\,Ag + 2\,Na_2SO_3 + 4\,Na_2S_2O_3 + 2\,H_2O$$

Most fixing bath treatment companies now use a process in which silver is recovered quantitatively by electrolysis. Fairly pure silver (90 – 99.5 %) is removed from the stainless steel cathodes in the form of sheets and budlike growths. In large laboratories and hospital X-ray departments, part of the silver is recovered continuously in electrolytic cells, so that the fixing bath can be used for a longer period and no longer need be discarded so frequently and replaced with new material. For smaller laboratories and doctors' surgeries, the recovery of silver from fixing baths is carried out by using containers packed with steel wool [74]. The spent fixing bath solution is run through slowly, whereby silver is reduced and precipitates on the steel wool. The suppliers take back the containers with the silver and send them to recovery plants.

Electrolysis equipment [75, 76] of various sizes is also rented out by many business establishments who undertake the refining and purchase of the silver produced. This system has become important mainly in European countries except Germany [77].

The complex-forming thiosulfate in the fixing bath can be decomposed by sodium hypochlorite or chlorine and neutralized with sodium hydroxide solution:

$$Na_2S_2O_3 + 4\,Cl_2 + 10\,NaOH \longrightarrow 2\,Na_2SO_4 + 8\,NaCl + 5\,H_2O$$

The silver chloride formed can be filtered off and reduced. In practice, oxidation with hydrogen peroxide is often preferred [78]. The advantages are ease and safety in handling, and the avoidance of contamination with toxic chlorinated organic substances. The reactions are

$$2\,Na_2S_2O_3 + H_2O_2 \longrightarrow Na_2S_4O_6 + 2\,NaOH$$

and

$$Na_2S_4O_6 + 7\,H_2O_2 + 6\,NaOH \longrightarrow 4\,Na_2SO_4 + 10\,H_2O$$

which can be summarized as

$$Na_2S_2O_3 + 4\,H_2O_2 + 2\,NaOH \longrightarrow 2\,Na_2SO_4 + 5\,H_2O$$

This can be taken to either the tetrathionate or the sulfate stage, depending on the desired BOD value of the wastewater produced. The silver precipitates as a mixture of Ag_2O, AgBr, and Ag_2S.

In low-silver fixing baths (e.g., washing baths or fixing baths from which silver has been removed electrolytically) the small amounts of residual silver can be removed by ion exchange [79–81].

5.9. Surface Desilvering

In silver-plated material for jewelry, the base metal is usually German silver, a copper–nickel–zinc alloy. The base materials of silver-plated electronic components are generally copper–iron, iron–nickel–cobalt alloys, or brass. In addition they contain tin as a brazing alloy component and gold as a contact material. In electrical low-current contacts, carrier materials for the silver coating can be copper, copper–tin, copper–beryllium, brass, German silver, or copper–nickel–tin.

The processing of these materials in the lead–silver smelting process (see Section 4.2) is uneconomical. The large amounts of copper result in formation of additional copper matte, which can often incorporate more silver than is introduced in the scrap material. Nickel and iron lead to the formation of undesired furnace bottoms. Silver-plated materials are better treated by the copper-smelting route (see Section 4.3), which allows recovery of copper, nickel, silver, and gold in high yield. A disadvantage is that the noble metal is tied up for a long period.

In the dissolution of silver coatings from metallic substrates by acid treatment, both silver and the base metal are attacked, especially in the reaction of nitric acid with German silver. A mixture of concentrated sulfuric acid and concentrated nitric acid gives better results. Silver-plated items may also be reacted with hot sodium polysulfide solution, which rapidly and selectively converts the silver to silver sulfide. The sulfide coating can then be removed by mechanical or thermal shock, or by reduction with aluminum or reducing agents, e.g.:

$$Ag_2S + Na_2S_2O_4 + 4\,NaOH \longrightarrow 2\,Ag + 2\,Na_2SO_3 + Na_2S + 2\,H_2O$$

The dissolution of silver coatings in sodium cyanide solution in the presence of oxygen is slow and therefore suitable only for very thin films (a few micrometers), such as those on electronic products. As with gold, higher rates of dissolution are achieved if water-soluble aromatic nitro compounds (e.g., nitrobenzenesulfonic acid or nitrobenzoic acid) are used as oxidizing agent instead of air [82]. When the base material consists of copper or copper alloys, unwanted side reactions of the type

$$Cu + 4\,NaCN + H_2O \longrightarrow Na_3[Cu(CN)_4] + NaOH + 1/2\,H_2$$

are difficult to avoid. Silver can be obtained from the resulting solution by electrolysis or by decomposition of the cyanide with chlorine.

5.10. Processing of Special Scrap

Silver residues for recovery often arise in combination with other valuable materials. In these cases, conventional processes may fail, either because the accompanying substances cause problems, or because they cannot be recovered. In many cases (e.g., Ag–α-Al_2O_3, Ag–W, Ag–Ta), silver can be dissolved by nitric acid without attacking the accompanying material. More reactive metals such as nickel, tin, cadmium, or indium can generally be dissolved – even if they are alloyed with silver – by using acid, acid mixtures, or alkali,or by anodic dissolution, leaving silver as the residue.

Before dental amalgam wastes are treated chemically to recover silver, they are usually heated to $>500\,°C$ in closed equipment with strict control of the surrounding atmosphere to distill the mercury.

6. Silver Refining [2,3,20,56,61,83]

Crude silver, from ores in primary production and from recycling operations generally has a purity of 98–99.5 %, which may include gold and platinum-group metals because these processes only separate noble metals from base metals.

The main task of silver refining (world output: 10 000 t/a) is the production of silver with

a purity of >99.9 % and >99.97 %. A purity of >99.99 % is increasingly being specified for industrial applications. The first and most important task is the recovery of gold and platinum metals from crude silver. The value of the gold in doré silver and auriferous silver often exceeds that of the silver itself. The refining of silver therefore generally includes a gold – silver separation process. Before refining, the noble metals are in very concentrated form, so the process must involve the shortest possible tying-up of the noble metal.

6.1. Fine Smelting

If the crude silver contains hardly any gold or platinum-group metals, silver of fineness 999/1000 can be obtained by an oxidation process, generally carried out in a separate refining furnace. The purification process is improved by adding alkali-metal nitrates, alkali-metal carbonates, or silver sulfate, and by blowing with oxygen.

6.2. Refining with Nitric Acid (Inquartation) [3]

The long-known process of dissolving a silver – gold alloy in nitric acid is still used today, although to a minor extent. Silver dissolves according to the equation

$$3\,Ag + 4\,HNO_3 \longrightarrow 3\,AgNO_3 + 2\,H_2O + NO$$

(see Fig. 2), and the gold remains undissolved. The separation becomes increasingly efficient as the composition of the alloy approaches Ag 75 Au25. Ag – Cu – Au alloys can also be treated by this process. In addition to silver, the base-metal components and considerable amounts of the platinum metals are dissolved. Silver nitrate can be isolated from the solution (see Section 7.1); metallic silver can be obtained by cementation and chemical reduction or electrolytic reduction; or silver chloride can be precipitated. Historically, the process was temporarily replaced by the sulfuric acid separation process, because of the high consumption of nitric acid and the large amount of recycled noble metal. Its advantage is rapid recovery of the gold. Hence alloys with high gold content (e.g., 10 – 20 %) are treated by this process.

6.3. Refining with Sulfuric Acid (Affination) [3]

Silver – gold alloys are treated with ca. 86 % sulfuric acid at 240 °C, whereby the silver is oxidized according to the equation

$$2\,Ag + 2\,H_2SO_4 \longrightarrow Ag_2SO_4 + 2\,H_2O + SO_2$$

and remains in solution as the more soluble silver hydrogensulfate. The solution is diluted with water to precipitate silver sulfate, which is filtered off and treated with iron in a cementation process. The silver sulfate still in solution is treated by cementation with copper to produce copper sulfate. This refining process can deal with a wider range of alloy compositions than the nitric acid process (Section 6.2). The alloys treated may contain appreciable amounts of copper. Also, the consumption of acid is much lower than in the nitric acid process. On the other hand, this refining process requires more costly equipment and results in considerable off-gas problems. The sulfuric acid process has not been used in large-scale applications since World War II.

6.4. Möbius Electrolysis [23, 24]

The Möbius electrolysis process for refining silver is used mainly in Europe (Fig. 7). A silver nitrate – sodium nitrate – nitric acid electrolyte is employed. Silver and the accompanying base metals are dissolved by anodic oxidation, and the concentration and current – voltage ratios are controlled so that only silver is deposited at the cathode. Cast crude silver anodes are suspended and surrounded by anode bags in which anode slime collects. This contains all the gold in the form of metal, selenide, or telluride, as well as platinum-group metals, silver particles that become detached, lead dioxide, and oxidic copper compounds. Dendritic silver crystals are deposited on the stainless steel cathode sheet and removed continuously by automatic scrapers to prevent short circuits. Copper accumulates in the electrolyte. If the concentration of copper becomes too high, it can deposit with the silver, and the purity specification may not be met. The

same is true of selenium. Palladium goes partly into solution but precipitates on the cathode to a very minor extent.

The silver concentration in the electrolyte is ca. 50 g/L, with 10 g/L of free HNO_3, and the anodic current density is 400 – 500 A/m^2. The cell voltage is 2.0 – 2.5 V. The anodes and cathodes are usually arranged in parallel in the cell, and the energy consumption is ca. 0.6 kW · h/kg of pure silver. To compensate for the anodically dissolved base metals that are not removed at the cathode (mainly copper), silver nitrate solution is fed into the electrolyte to prevent depletion of silver.

Figure 7. Silver electrorefining by the Möbius process
a) Scraper; b) Cathode (stainless steel); c) Anode (crude silver); d) Anode bag; e) Anode slime (gold, platinum-group metals); f) Silver crystals; g) Scraper

At one time, the Möbius process had to be interrupted to remove crystals of fine silver. The anode and cathode carrying device was lifted from the bath, and the perforated false bottom was raised to enable the silver crystals to be collected. Today, cells are usually constructed so that the silver crystals can be scraped manually over the edge of the vessel without interrupting electrolysis (Fig. 7). The spent anodes are replaced continually by new anodes, so that interruption of electrolysis is necessary only if the electrolyte must be replaced due to excessive copper concentration, or if the anode bags have to be emptied. The electrolyte is usually treated with copper to recover the silver by cementation, and the copper is then recovered by cementation with iron. The electrolyte can also be treated by chemical precipitation methods or by the "black melt" process in which a mixture of silver nitrate and copper nitrate is obtained by evaporating to dryness (see Section 7.1). The main accompanying metal, copper, is reported to be removed by liquid – liquid extraction, in which case the remaining silver-containing solution could then be returned to the system [84, 86, 85].

The Möbius electrolysis process is most suitable for crude silver containing >90 % Ag. With high copper content, the electrolyte must be regenerated too often, and with high gold content, the anode bags require frequent emptying. Both are costly operations. A single electrolysis gives a purity of 99.95 – 99.99 % Ag and a double electrolysis gives a purity of 99.995 – 99.999 %.

Current developments in silver electrolysis are aimed at fully automated high-speed cells which are able to process higher gold and PGM contents. Possibilities are the application of high Au contents (up to 25 – 30 %) so that a Au/PGM scaffold remains from the anode, or the use of alloy grains. In the latter case the process works at higher currents (same current density). Feeding of silver grains and removal of anode-slime can be automated by special anode-cell constructions.

6.5. Balbach – Thum Electrolysis [23, 24]

The Balbach – Thum electrolysis process uses virtually the same electrochemical conditions as the Möbius process. Only the geometrical arrangement is different (see Table 5 and Figure 8). The anodes and cathodes are arranged horizontally. Each cell is provided with only one anode and one cathode. The cathode is a stainless steel plate covering the entire floor area. Above this, at a distance of 10 cm, is a slightly smaller framework of nonconducting material, covered with fabric and containing the anodes. The anode and cathode are supplied with electric cur-

rent via silver contacts. The crude silver anodes are completely covered by electrolyte, and therefore completely dissolved, unlike the anodes of the Möbius process, which leave behind some unconsumed metal. Another advantage of Balbach – Thum electrolysis is that the anode slime is recovered more easily, which is especially important when the crude silver has a high gold content. Disadvantages include the large space requirement and high energy consumption. The Balbach – Thum process is used mainly in the United States.

Figure 8. Balbach – Thum electrorefining

7. Silver Compounds [20, 87–89]

7.1. Silver Nitrate [2]

Properties. Silver nitrate [*7761-88-8*], M_r 169.87, theoretical silver content 63.50 %, colorless rhombic crystals, *mp* 209 °C, temperature of transformation to the trigonal form 160 °C, decomposition temperature 444 °C, density 4.352 g/cm^3, is very soluble in water, the solubility being strongly dependent on temperature (see Table 5 and Fig. 9), with complete miscibility in the $AgNO_3 - H_2O$ system at >159 °C. Its solubility in water is decreased considerably by the presence of nitric acid (see Fig. 2). The solubility in ethanol is 20.8 g/L, in methanol 35 g/L, and in benzene 2.2 g/L.

Silver nitrate has an oxidizing action on organic materials, which can lead to ignition and combustion, sometimes with explosion. Silver nitrate is decomposed even by traces of dust, with formation of finely divided, black silver. The reaction is accelerated by light. Silver nitrate and its solutions are unstable toward light over long periods. Complete drying after production leeds to instable material. Traces of acid on the surface can prevent decomposition for longer terms.

Figure 9. Correlation between concentration and density in aqueous silver nitrate solution at 20 °C

Production. Silver nitrate is generally produced by dissolving pure silver in hot 32 % nitric acid:

$$4\,Ag + 6\,HNO_3 \longrightarrow 4\,AgNO_3 + NO + NO_2 + 3\,H_2O$$

If all the nitrogen dioxide is recycled by reaction with the water in the system to form nitric acid (see below), the overall reaction is

$$3\,Ag + 4\,HNO_3 \longrightarrow 3\,AgNO_3 + NO + 2\,H_2O$$

In practice, the mass balance lies somewhere between these two equations. A slight excess of nitric acid is required, which can be recovered when the product is crystallized by evaporation. Many producers pass oxygen or air through the reaction mixture, giving improved recovery of nitric acid:

$$4\,Ag + 4\,HNO_3 + O_2 \longrightarrow 4\,AgNO_3 + 2\,H_2O$$

However, the formation of nitrogen oxides can be largely suppressed by using a closed vessel, so that off-gas treatment can be avoided. The nitrogen oxides produced were formerly thermally decomposed at >600 °C in a flame, to produce nitrogen and oxygen, but energy costs are high. An alternative method is to use the reactions

$$2\,NO + O_2 \longrightarrow 2\,NO_2$$

and

$$3\,NO_2 + H_2O \longrightarrow 2\,HNO_3 + NO$$

Table 5. Saturated solutions of silver nitrate in water

Temperature, °C	$AgNO_3$, g per 100 ml H_2O	$AgNO_3$, g/L of solution	$AgNO_3$ molarity	$AgNO_3$, wt %	Density, g/cm^3

> 159	∞				

or the direct reaction

$$2\,NO_2 + H_2O_2 \longrightarrow 2\,HNO_3$$

These processes are best carried out in countercurrent gas scrubbing equipment. The nitric acid formed is recycled to the process.

Since silver nitrate for the photographic industry is of a purity higher than that of refined silver, purification is required. Typical silver nitrate quality for photographic industry (in ppm) is given below:

Pb	≤ 0.2
Cu	≤ 0.2
Fe	≤ 0.2
Cd	≤ 0.2
Hg	≤ 0.01
Cr	≤ 0.2
Mn	≤ 0.2
Ni	≤ 0.2
Al	≤ 0.5
Sb	≤ 0.1
Bi	≤ 0.1
Se	≤ 0.1
Sn	≤ 0.1
Zn	≤ 0.1
K	≤ 5
Na	≤ 5
Ca	≤ 1
Pt	≤ 0.001
Pd	≤ 0.005
Au	≤ 0.005
Rh	≤ 0.001
Ir	≤ 0.001
Ru	≤ 0.001
Sulfate	≤ 20
Nitrite	≤ 10
Chloride	≤ 5

The classical crystallization process is in principle very effective, but due to the high solubility of silver nitrate even in the cold (see Table 5) and in the presence of HNO_3 (see Fig. 2), the amount recycled is high. Nevertheless, consequtive crystallization steps are the main purification process in the photographic industry. Precipitation and adsorption of copper, iron, lead, tin, etc., as their oxide-hydrates by the addition of silver(I) oxide are recommended. This is added to the weakly acid aqueous solution until the pH reaches 6. Chromatographic purification methods based on γ-Al_2O_3 have also been described [90, 91]. Small traces of compounds of the platinum-group metals can lead to undesirable photochemical sensitization and can be converted into the inactive elemental form by irradiation with UV light [92]. Final purification can be carried out by heating molten anhydrous silver nitrate to ca. 350 °C, which mainly removes copper [20, 36]. At this temperature, silver nitrate does not decompose to the nitrite, but the decomposition temperature of most other heavy-metal nitrates to their oxides is exceeded. The copper oxide formed gives a dark-colored melt (black melt process). Precipitated impurities are removed by dissolving the product in water and filtering. The purified solution is then concentrated, and the silver nitrate is crystallized, washed carefully, and dried.

In the production of silver nitrate on an industrial scale, the equipment must be closed so that no loss of silver nitrate solution, aerosols, or dusts occurs. All operations can be carried out in stainless steel equipment.

Figure 10. Solubilities of silver compounds in water as a function of temperature

The silver may be recovered from the mother liquor by cementation on copper, or the mixed nitrates can be treated by the black melt process to separate silver and copper. Alternatively, silver may be precipitated as silver chloride.

Uses. Most of the silver nitrate produced commercially is used in the photographic industry (see Section 10.10, and → Photography). Therefore, the quality specification for this application is the one in general use. Silver nitrate is also the starting material for the production of most other silver compounds and preparations, e.g., potassium dicyanoargentate(I) (see page 34), silver oxide (see Section 7.3), and supported catalysts. The process of electroless silver plating is also based on silver nitrate (see Section 10.5). Approximately 33 % of the worldwide annual consumption of industrial silver (ca. 22 000 t) is in the form of silver nitrate.

7.2. Silver Halides

Silver chloride [*7783-90-6*], AgCl; silver bromide [*7785-23-1*], AgBr; and silver iodide [*7783-96-2*], AgI (see Table 6 and Fig. 10) resemble one another in properties. Silver astatide (AgAt) is a member of this series, although it is likely to be sensitive to oxidation, even by atmospheric oxygen [93].

Silver halides become increasingly insoluble in the series AgCl, AgBr, AgI. Their solubility can be reduced further by addition of the respective common ion in low concentration. Higher concentrations of the common ion cause a marked increase in solubility due to the formation of complexes of the type $[AgX_2]^-$ (see Fig. 4). Soluble complexes are also formed with thiosulfate, cyanide, and ammonia (see Section 7.6). Solubility in organic solvents increases with increasingly nonpolar character of the chemical bond from chloride to iodide.

All three compounds are sensitive to light and are used in photographic coatings on film and paper (see Section 10.10 and → Photography). Other industrial applications of silver halides are much less important.

Silver halides are produced almost exclusively by precipitation from aqueous silver nitrate solution by the addition of solutions of

Table 6. Properties of the sparingly soluble halides and pseudohalides of silver

[a] The isomeric compounds corresponding to the tautomeric formulas H−N≡C, H−O−C≡N, H−N=C=S, and H−O−N≡C, are not known in all cases, or the isomerism is not well defined in the solid state; the nomenclature used in the literature is contradictory [20,98,100].

[b] High-temperature and high-pressure modifications also generally exist.

[c] Hexamethylphosphoric triamide.

alkali-metal halides. Synthesis from the elements is also possible [94–96]. In the temperature range between the melting points of the metal and the halide, silver chloride, in particular, can be produced readily and economically.

7.3. Silver Oxides [2]

Silver(I) oxide [*20667-12-3*], Ag_2O, M_r 231.74, theoretical silver content 93.10 %, silver content of commercial product 93.0 %, ϱ 7.143 g/cm^3, is a dark brown powder with cubic crystal structure. It decomposes slowly at ca. 150 °C and rapidly at 300 °C.

Silver(I) oxide is formed when alkali-metal hydroxides are added to solutions of silver salts such as silver nitrate. Silver hydroxide cannot be isolated as an intermediate product (but can be detected visually as a white pricipitate before it turns dark brown), although an aqueous suspension of the sparingly soluble silver(I) oxide in water has a marked alkaline reaction. In electrolytes containing sodium hydroxide or in neutral electrolytes that do not produce sparingly soluble silver salts, silver(I) oxide can be produced by anodic oxidation of metallic silver.

Silver(I) oxide is used in considerable quantities (i.e., several hundred tons per year) in batteries (see Section 10.5). In organic synthesis, it is used to replace halogen atoms with OH groups.

Silver(II) oxide [*1301-96-8*], AgO, M_r 123.87, theoretical silver content 87.08 %, AgO content of commercial product 97.5 %, is now known to have the composition $Ag^{I}Ag^{III}O_2$. It is a gray-black powder, with a monoclinic crystal structure, which decomposes slowly to the elements above ca. 85 °C and rapidly above 100 °C. Silver(I) oxide has not been detected as an intermediate of this reaction.

Silver(II) oxide is usually prepared by the oxidation of monovalent or elemental silver by peroxodisulfate [97]. Other suitable oxidizing agents are potassium permanganate, ozone, sodium hypochlorite, or an electric current. Silver(II) oxide is a strong oxidizing agent. In contact with organic compounds, including solvents, spontaneous reaction can occur. It is increasingly used in voltaic cells (see Section 10.5), where the amount of electricity produced per mole of silver(II) oxide reacted is twice that produced per mole of silver(I) oxide, leading to economies in weight and space. The lower silver consumption means it is often more economical to use silver(II) oxide than silver(I) oxide, despite higher production costs.

7.4. Other Soluble Silver Compounds

Silver sulfate [*10294-26-5*], Ag_2SO_4, M_r 311.82, silver content 34.60 %, *mp* 657 °C, ϱ 5.45 g/cm^3, is a white, crystalline salt with rhombic structure. It is fairly soluble in water (see Fig. 10) and more soluble in sulfuric acid (see Fig. 2), forming $AgHSO_4$, which can be isolated. Silver sulfate is produced by the reaction of silver with hot, concentrated sulfuric acid.

$$2\,Ag + 2\,H_2SO_4 \longrightarrow Ag_2SO_4 + SO_2 + 2\,H_2O$$

It can also be prepared by precipitation with sulfuric acid from $AgNO_3$ solution, followed by recrystallization from dilute sulfuric acid.

Silver permanganate [*7783-98-4*], $AgMnO_4$, M_r 226.81, silver content 47.60 %, is a black-violet salt that is moderately soluble in water (see Fig. 10). It can be used as a disinfectant and oxidizing agent. It is produced as the least soluble component in the system

$$AgNO_3 + KMnO_4 \longrightarrow AgMnO_4 + KNO_3$$

or by the reaction of silver(I) oxide or silver carbonate with a solution of permanganic acid. It tends to decompose if it is completely dry.

Silver(I) fluoride [*7775-41-9*], AgF, M_r 126.88, silver content 87.79 %, *mp* 434 °C, ϱ 5.852 g/cm^3, is a white, flaky, crystalline solid with cubic crystal structure. It is hygroscopic and soluble in water. With increasing temperature, the solid phases $AgF \cdot 4\,H_2O$ and $AgF \cdot 2\,H_2O$ exist in equilibrium with the saturated solutions.

Silver fluoride is prepared by the reaction of silver(I) oxide or silver carbonate with hydrofluoric acid, or by dissolving finely divided precipitated silver powder in hydrofluoric acid and hydrogen peroxide.

Silver fluoride is of minor industrial importance but is used in preparative fluorine chemistry.

Disilver fluoride, Ag_2F, is water sensitive, and silver(II) fluoride, AgF_2, is highly reactive.

Silver tetrafluoroborate [*14104-20-2*], $Ag[BF_4]$, is used in aqueous solution as an absorbent for ethylene. It can be produced in benzene

$$AgF + BF_3 \longrightarrow Ag[BF_4]$$

or in aqueous solution

$$Ag_2O + 2\,H[BF_4] \longrightarrow 2\,Ag[BF_4] + H_2O$$

The compound is very hygroscopic and unstable to light.

Oxy Salts of Halogens. Silver chlorate [*7783-92-8*], $AgClO_3$, is moderately soluble in water, and silver perchlorate [*66259-09-4*], $AgClO_4$, is very soluble.

Soluble Organic Silver Compounds. Silver(I) acetate [*563-63-3*] (see Fig. 10), silver(I) propionate [*5489-14-5*], and silver(I) lactate [*15768-18-0*] are fairly soluble in water.

Silver(I) behenate is used in the Dry-Star copy process (Agfa).

7.5. Other Insoluble Silver Compounds [98]

Silver sulfide [*21548-73-2*], Ag_2S, M_r 247.80 %, *mp* 845 °C, ϱ 7.326 g/cm^3, silver content 87.06, forms black crystals or powders with monoclinic crystal structure (as argentite, cubic), and is the least soluble silver compound (7×10^{-14} g/L at 20 °C). It is not dissolved by the ligands ammonia and thiosulfate, but is dissolved by cyanide. Silver sulfide can be dissolved by oxidative reactions (e.g., in hot, concentrated nitric acid). It can be reduced by base metals or by dithionite in alkaline solution. The latter is used to remove the dark coating from tarnished silver.

Silver sulfide is prepared from the elements at 250 – 400 °C or by precipitation of silver by sulfide ions.

Silver carbonate [*534-16-7*], Ag_2CO_3, M_r 275.75, ϱ 6.077 g/cm^3, is a white powder that rapidly turns yellow. It has a monoclinic crystal structure and decomposes at 218 °C, liberating carbon dioxide. It is prepared from soluble silver compounds by precipitation with alkali-metal carbonate and is used in considerable amounts in the production of silver powder.

Silver isocyanate, AgNCO, M_r 149.89, can be precipitated from aqueous solution. A mainly covalent Ag – N bond is present in AgNCO. Silver cyanate, AgOCN, apparently does not exist. Unlike the isomeric silver fulminate, AgCNO (see Section 7.7), silver isocyanate is thermally stable. The nomenclature for cyanates and isocyanates is, however, not yet uniform [20, 98–100].

Silver cyanide [*506-64-9*], AgCN, M_r 133.89, *mp* 350 °C, ϱ 4.62 g/cm^3, is a white powder with a trigonal crystal structure. It is prepared from soluble silver salts by precipitation with cyanide anions. This compound is the precursor in the production of potassium dicyanoargentate(I). Silver cyanide used to be important in analytical chemistry because of its low solubility in water, and the ease and rapidity with which it can be converted into the dicyanoargentate complex.

Silver thiocyanate [*1701-93-5*], AgSCN, M_r 165.95, ϱ 3.746 g/cm^3, is a white powder with a monoclinic crystal structure that decomposes on melting. It is produced by precipitation from aqueous solution, a reaction that is also used in quantitative analysis (see Chap. 11).

7.6. Silver Complexes

Potassium dicyanoargentate(I), $K[Ag(CN)_2]$, M_r 199.01, silver content 54.20 %, ϱ 2.364 g/cm^3, forms white crystals with trigonal structure, which are very soluble in water (see Fig. 10) and fairly soluble in ethanol. It is prepared by dissolving silver cyanide in an aqueous solution of KCN, concentrating by evaporation, and crystallizing. It can also be obtained electrolytically by the anodic oxidation of silver in aqueous potassium cyanide solution. This method is analogous to that for the preparation of $K[Au(CN)_2]$ (see → Gold, Gold Alloys, and Gold Compounds, Chap. 7.1.). Potassium dicyanoargentate is the basis of cyanide plating baths (see Section 10.5) and is used extensively in the jewelry industry.

The corresponding sodium salt has similar properties and is an intermediate in the extraction of silver from ores by the cyanide process (see Chap. 4).

Thiosulfate Complexes. Several complexes are known, for example,

$$Na[Ag(S_2O_3)] = Na_2S_2O_3 \cdot Ag_2S_2O_3$$
$$Na_4[Ag_2(S_2O_3)_3] = 2\,Na_2S_2O_3 \cdot Ag_2S_2O_3$$
$$Na_3[Ag(S_2O_3)_2] = 3\,Na_2S_2O_3 \cdot Ag_2S_2O_3$$
$$Na_5[Ag(S_2O_3)_3] = 5\,Na_2S_2O_3 \cdot Ag_2S_2O_3$$

All these take part in the photographic fixing process (see Section 10.10) but have no technical importance in their own right. Their solubility in water increases as the ratio of $S_2O_3^{2-}$ to silver in the complex increases.

Diammine Complexes. The cationic complex $[Ag(NH_3)_2]^+$ is formed when most silver compounds are dissolved in aqueous ammonia. The solution is unstable (especially when produced at pH > 10, e.g., by addition of NH_4OH solution to silver(I) oxide) and can precipitate highly explosive fulminating silver (see Section 7.7).

7.7. Explosive Silver Compounds [101]

Many unstable silver compounds are known whose decomposition can occur spontaneously and explosively. This reaction is usually initiated by heat, pressure, impact, or abrasion. These unstable silver compounds are all light sensitive. Hence, high-energy flashes of light can also occasionally cause explosive decomposition. Such compounds are no longer used to any extent, or are used only for very special preparative work, partly because of the near impossibility of storing them safely. Nevertheless, they can be formed in many chemical reactions and processes and, if their existence and properties are unrecognized, can result in accidents.

Silver azide [*13863-88-2*], AgN_3, M_r 149.89, silver content 71.97 %, has colorless, needle-like crystals (*mp* 252 °C). It is an extremely explosive compound, sensitive to heat, impact, and pressure.

Silver azide is insoluble in water and can be obtained by precipitation from solutions of sodium azide and silver nitrate. It can be used to prepare the equally explosive iodine azide (IN_3):

$$AgN_3 + I_2 \longrightarrow IN_3 + AgI$$

It is less stable than lead azide and has therefore not been used as a detonator.

Fulminating silver forms black crystals that consist of a mixture of silver nitride, Ag_3N, and silver imide, Ag_2NH. It is formed when aqueous ammoniacal solutions of silver compounds are stored, and by the action of ammonia on silver oxide or silver carbonate.

An explosion can be caused by slight movement of a vessel containing an aqueous solution in which a small amount of fulminating silver has precipitated and collected at the bottom. Aqueous solutions containing $[Ag(NH_3)_2]^+$ should therefore never be stored.

Silver amide [*65235-79-2*], $AgNH_2$, is highly explosive. It is formed mainly by the reaction of silver compounds with liquid ammonia. Silver fittings or equipment should therefore not be used in contact with liquid ammonia.

Silver fulminate [*5610-59-3*], AgCNO, is the silver salt of fulminic acid, HCNO [98, 102], and is sometimes also referred to as fulminating silver (see above). It forms white needles that explode under mechanical or thermal stress, and is considerably less stable than mercury fulminate.

Silver acetylide [*7659-31-6*], Ag_2C_2, is an amorphous compound that decomposes explosively on impact or heating. On treatment with alkali-metal hydroxides, hydrolytic decomposition takes place.

Silver acetylide is prepared by passing acetylene into an ammoniacal solution of silver salts. If acetylene is passed into a neutral solution of silver nitrate, crystalline addition compounds, such as $Ag_2C_2 \cdot AgNO_3$ or $Ag_2C_2 \cdot 6\,AgNO_3$, are precipitated. Explosive silver acetylide is also formed when silver compounds come in contact with an acetylene flame. The existence of this hazard is the reason acetylene flames are not used for the excitation of silver in solution for spectral analysis. Apparatus and containers for acetylene should not include fittings or components made of silver or high-silver alloys. Conventional silver brazing alloys are safe.

Silver oxalate [*533-51-7*], $(COOAg)_2$, M_r 303.76, is a white compound that is insoluble in water and can be prepared by precipitation. It is temperature sensitive and decomposes on gradual heating, but detonates if heated rapidly.

8. Disperse Silver [18,20,58,102]

8.1. Silver Powder

Silver powder is classified as microcrystalline, spheroidal, or lamellar (flakes and bronzes), according to its particle shape. All three types, which differ in method of manufacture, have specific areas of use. The basic material is pure silver or combinations of silver and palladium.

For various applications, the following properties are important: bulk density, tapped density, and tamped density (see Table 7), sinterability, flow properties, densities achievable by compression and sintering, specific surface area, and content of impurities such as Na^+, K^+, and Cu^{2+}. These properties depend ultimately on particle shape and size, and on particle-size distribution. The size of the primary particles is not identical to the particle size measured by particle-size analysis, especially for dendritic powders in which agglomerates often occur. Earlier quality specifications were based mainly on sieve analysis, which has now largely been replaced by laser granulometry. The latter gives a value for particle size such that a defined fraction of the material (e.g., 90 %) is finer than the quoted particle size. Methods for particle-size analysis are being supplemented more and more by optical and scanning electron microscopy.

Microcrystalline Silver Powder. Several basic types of microcrystalline silver powder are available, differing in method of preparation, type of particle, and properties (see Table 8). They were used almost entirely in sintering technology for a long time. Later, they were also used in stoving preparations (e.g., metallization of ceramics) and in pastes for repairing heated rear windows of motor vehicles.

The most important method of production is precipitation by reducing agents, such as formaldehyde, potassium sodium tartrate, and hydrazine, from solutions of silver nitrate in dilute sodium hydroxide solution. Alternatively, Ag_2O or Ag_2CO_3 suspensions are sometimes reduced with these reducing agents.

Cementation with less noble metals is no longer of practical importance because of contamination of silver with the precipitating metal and wastewater problems.

Electrolytic reduction of silver nitrate solutions under conditions used in Möbius electrolysis (see Section 6.4) leads to a coarsely crystalline product that is not generally regarded as a silver powder and is marketed as "crystal silver." However, by using special methods of scraping or washing the cathode and varying the conditions, the electrolysis of silver nitrate can be made to yield a finely powdered material suitable for sintering applications. Electrolysis of an acidic medium has the advantage that base metals are not usually deposited with the silver. This allows less pure starting materials to be used [103]. Cathodic reduction of semiconducting silver(I) oxide in a medium containing sodium hydroxide leads to finely divided silver powder that is very similar to the chemically precipitated product. Silver oxide can be obtained by precipitation or by oxidation of a silver anode and deposition of the oxide on the cathode. Also, thermal decomposition of silver(I) oxide or silver carbonate gives a silver powder with a relatively small specific surface area.

Spheroidal Silver Powder. Atomization of molten silver by compressed air, inert gas, a water jet, or a rapidly rotating knife produces spheroidal silver powder, which is used mainly in sintering technology. It is characterized by relatively high bulk density, low specific surface area, and good flow properties.

Flakes and Bronzes. Lamellar particles are obtained by ball milling microcrystalline silver powder. Flakes and bronzes are incorporated into paints and adhesives, where they impart electrical conductivity to the polymer matrix due to the good particle-to-particle electrical contact.

Silver – palladium powder is used in the production of conducting electrodes in ceramic multilayer capacitors. Palladium improves the migration resistance. Several types of powder are produced by different methods, including

mixtures of silver and palladium powders (composite blends), simultaneously precipitated Ag – Pd powders (coprecipitates), and alloy powders (solid solutions). Examples of these stoving powders are given in Table 9.

8.2. Colloidal Silver [2, 20, 87, 104]

Like most noble metals, silver forms very stable colloidal solutions in water.

Table 9. Silver – palladium powders for multilayer capacitors

Producer	Product no.	Composition, %	Particle shape	Tapped density, g/cm^3	Particle size, µm	Specific surface area, m^2/g

	3070	Ag 30 Pd 70	spheroidal	1.5 – 2.3	< 3.5	1.9 – 3.0

Properties typical of colloids are observed mainly for the particle-size range 0.001 – 0.1 µm. Fine-grained photographic emulsions can also consist of dispersions of colloidal dimensions. Most commercial silver colloids have an average particle size between 0.01 and 0.05 µm, corresponding to specific surface areas between 50 and 250 m^2/g silver. The use of silver sols in medicine (see Section 10.3) and for the disinfection of water (see Section 10.11) is due to the high reactivity of silver resulting from its large surface area.

As with all colloidal solutions of metals in water, the stability of the solution is maintained by the negative charge on the metal particles and their consequent mutual repulsion. The negative charge is caused by the adsorption of anions. If it is disturbed by aging or by the adsorption of electrolytes until the isoelectric point is reached, partial or complete coagulation and flocculation occur.

Aging and the effects of electrolytes can be inhibited by adding protective colloids, generally naturally occurring polymers. These can still be effective after the dispersant has evaporated, allowing the powder left behind to produce a colloidal solution on rewetting. Such reversible colloids are often preferred to colloidal solutions because of ease of handling.

Colloidal silver is generally produced by reduction of a dilute solution of silver nitrate by the usual reducing agents (e.g., formaldehyde, hydrazine) at elevated temperature. Polymers that behave both as protective colloids and contain reducing groups can also be used [105]. A silver sol can also be produced by the electrical dispersion of compact metallic silver immersed in water. Commercial silver sols usually have concentrations of ca. 1 % silver. Their color by transmitted light varies between yellow and brown, and they show green to blue fluorescence effects by reflected light. Colloidal silver powder, which is black and granular, has a silver content varying between 75 and 97 %. On redispersion in water, dark brown to black colors are obtained.

9. Silver Alloys [2, 18, 24, 106–112]

The binary alloys of silver can be divided into groups according to their alloying behavior (Fig. 11) [2, 19, 113].

9.1. Binary Silver Alloys [114–117]

Phase diagrams of binary silver alloys according to Massalski [118] are shown in Figures 12 (Ag – Al), 13 (Ag – Au), 14 (Ag – Cd), 15 (Ag – Cu), 16 (Ag – Ga), 17 (Ag – Ge), 18 (Ag – Hg), 19 (Ag – In), 20 (Ag – Li), 21 (Ag – Mg), 22 (Ag – Mn), 23 (Ag – Ni), 24 (Ag – O), 25 (Ag – Os), 26 (Ag – P), 27 (Ag – Pb), 28 (Ag – Pd), 29 (Ag – Pt), 30 (Ag – Rh), 31 (Ag – Ru), 32 (Ag – Si), 33 (Ag – Sn), 34 (Ag – Ti), and 35 (Ag – Zn). The most important binary silver alloys are described below.

Silver – Copper (Fig. 15). The Ag – Cu alloys are commercially the most important silver alloys. Almost all coinage and jewelry silver (Tables 10 and 11) consists of silver – copper alloys. AgCu eutectic alloys are widely used for vacuum brazing [19].

The two components are completely miscible in the liquid state but have limited solubil-

Figure 11. Grouping of binary silver alloys in the periodic table

Figure 12. Phase diagrams of binary silver alloys: Ag – Al

ity in the solid state. At the eutectic temperature (780 °C), 8.8 wt % (14.1 atom %) copper dissolves in silver, and 8.0 wt % (4.9 atom %) silver in copper. At 200 °C, only 0.2 wt % copper dissolves in silver, and 8.0 wt % (4.9 atom %) silver in copper. At 200 °C, only 0.2 wt % copper dissolves in silver, and < 0.05 wt % silver in copper. At the eutectic point, the composition is 71.9 wt % (60.1 atom %) silver and 28.1 wt % (39.9 atom %) copper. Hence, in practice, all industrially important silver – copper alloys lie on the silver-rich side of the eutectic composition.

The industrial use of silver – copper alloys is based on the fact that many of their properties are satisfactory over a wide range of concentrations [2].

The color of silver is influenced by the presence of even small amounts of copper. Up to a weight ratio of 1 : 1, the alloys are almost white. Above ca. 68 % copper, they are red, and in bet-

Figure 13. Phase diagrams of binary silver alloys: Ag – Au

Figure 14. Phase diagrams of binary silver alloys: Ag – Cd

ween they are pale red. The shades of color, however, depend very much on the structure of the alloy and hence on its method of formation. Color variations in electrolytically deposited alloy coatings are extremely dependent on the type of electroplating bath used.

The phase relationships in the range of industrial silver – copper alloys allow the lattice structure and properties to be modified by thermal treatment. If a melt with composition Ag 925 Cu 75 (sterling silver) is allowed to cool slowly to the solidification point (915 °C) and held around this temperature, a homogeneous mixed crystal is formed in which the silver lattice positions are occupied by copper in a statistically random distribution (substitution mixed crystal). If the alloy is then quenched rapidly, the single mixed-crystal phase is retained, and the resulting alloy is ductile. If a melt of sterling silver is cooled more slowly (e.g., under the conditions of an industrial casting operation), a proportion of mixed-crystal phase is obtained together with precipitated eutectic phase. With decreasing temperature, the solubility of copper in silver decreases, and a copper-rich phase separates, leading to precipitation hardening. For

Figure 15. Phase diagrams of binary silver alloys: Ag – Cu

Figure 16. Phase diagrams of binary silver alloys: Ag – Ga

the same reason, ductile sterling silver with a high mixed-crystal content can be hardened by tempering at 300 °C. Ductile sterling silver is also formed by very slow cooling; the structure consists of almost pure silver and copper phases. The mechanical properties of other commercially important silver – copper alloys can be modified by similar treatment.

Silver – Cadmium. Mixed crystals are formed without miscibility gaps on the silver-rich side of the Ag – Cd system, up to a cadmium content of at most 43.2 wt % (see Fig. 14). All industrial alloys lie in this range. The existence of yellow, reddish, and violet hues in the range 40 – 60 % Cd is noteworthy.

Due to the toxicity of cadmium, the use of Ag – Cd alloys as materials for electrical contacts is now of only minor importance. They have been replaced to a large extent by silver composite materials, for example $AgSnO_2$ materials. However, to produce Ag – CdO composites (e.g., Ag – CdO: 90/10 and Ag – CdO: 85/15) by inner oxidation, the corresponding Ag – Cd alloys must first be produced [58]. Special safety precautions must be taken when the alloy is

Figure 17. Phase diagrams of binary silver alloys: Ag – Ge

Figure 18. Phase diagrams of binary silver alloys: Ag – Hg

melted because of the high toxicity of both cadmium vapor and the readily formed cadmium oxide aerosol. Cadmium (*mp* 320.9 °C, *bp* 767 °C) has a high vapor pressure.

Silver – Gold. Silver and gold form mixed crystals without miscibility gaps (see Fig. 13). Neither separation nor transformation occurs in any part of the system. Binary silver – gold alloys are of little interest as construction materials because of their low hardness.

Silver – Palladium (Fig. 28). Apart from gold, palladium is the only metal that forms mixed crystals with silver without miscibility gaps. The alloy Ag 23 Pd 77, which is used for hydrogen diffusion membranes, exhibits extremely high hydrogen permeability and high dimensional stability.

Silver – Nickel. The extremely low mutual solubility of silver and nickel (see Fig. 23) is utilized industrially in the production of Ag – Ni composite metal by powder metallurgical processes. AgNi alloys with low Ni contents (ca.

Figure 19. Phase diagrams of binary silver alloys: Ag – In

Figure 20. Phase diagrams of binary silver alloys: Ag – Li

0.15 %) can be produced by melting and casting, which lead to fine-grained silver.

Silver – Lead. Because of the eutectic in the Ag – Pb system (see Fig. 27), careful cooling of a lead alloy with a very low silver content in the region of the eutectic temperature causes relatively pure lead to separate as a solid until the content of the melt reaches 2.7 wt % (4.5 atom %) silver. This is the basis of the Pattinson process for the enrichment of silver in lead (see Section 4.2).

Other Binary Silver Alloys Used Industrially. The systems Ag – Zn (Fig. 35) and Ag – Hg (see Fig. 18) are important in silver extraction (see Section 4.2), and Ag – Hg is also important in dental technology (see Section 10.4), although ternary and even higher systems are more important.

In brazing, binary alloys of silver with aluminum, beryllium, indium, manganese, lithium, and titanium, are sometimes used as prealloys. Lithium and titanium promote wettability of the metal by the brazing alloy.

Because of the high solubility of silver in molten sodium, silver equipment or silver-containing brazing alloys must not come in contact

Figure 21. Phase diagrams of binary silver alloys: Ag – Mg

Figure 22. Phase diagrams of binary silver alloys: Ag – Mn

with sodium metal. Small quantities of Mg or Si in the silver increase its hardness.

9.2. Ternary Silver Alloys

Ternary silver alloys are of greater industrial importance than binary alloys, the only important exception being the system Ag – Cu. Alloys containing three or more components allow a wide range of mechanical, and electrical properties to be obtained. For metals that either do not alloy with silver or do so to only a limited extent in binary systems, the presence of a third component often makes alloy formation possible. A knowledge of three component alloys often leads to the experimental development of alloys containing four or more components.

The ternary alloys of silver have been investigated extensively [110–113, 119].

Silver – copper – gold is a very important system in jewelry alloys (see →Gold, Gold Alloys, and Gold Compounds, Chap. 8.2.), almost exclusively in the gold-rich region. These alloys exhibit a wide range of hardness and color.

Figure 23. Phase diagrams of binary silver alloys: Ag – Ni

Figure 24. Phase diagrams of binary silver alloys: Ag – O

Silver – tin – mercury is the basis of the technology of dental amalgams (see Section 10.4).

Silver – Lead – Zinc. Formation of the silver-containing zinc crust in the Parkes process for the extraction of silver from ores (see Section 4.2.4) takes place essentially in this ternary system.

Silver – lead – gold alloys are present in the lead shaft furnaces of noble-metal recycling smelters. However, the entire process takes place in the molten state, so that phase relationships in the solid state are of little importance.

Silver – Copper – Phosphorus. Some hard solders with a low silver content, used without flux, are ternary systems of the type Ag – Cu – Cu_3P.

Silver – Copper – Zinc. Brazing alloys with low melting temperatures exist among the Ag – Cu – Zn alloys. L-Ag44 consist of 44 % Ag, 30 % Cu and 26 % Zn and has a melting range of 680 – 740. Even lower melting ranges can be achieved in the AgCuZnSn systems.

Figure 25. Phase diagrams of binary silver alloys: Ag – Os

Figure 26. Phase diagrams of binary silver alloys: Ag – P

Silver – Cadmium – Indium. The alloy Ag 80 Cd 5 In 15 has been used to control nuclear reactors. It combines a high thermal neutron capture cross section with high thermal conductivity, mechanical stability, and good corrosion resistance toward hot water.

9.3. Quaternary Silver Alloys

Commercial quaternary silver alloys include brazing alloys, which belong mainly to the Ag – Cu – Zn – Sn system, and modern gold-colored dental alloys, which generally contain palladium or platinum in addition to Au – Ag – Cu [19].

9.4. Manufacturing [18, 23, 24, 58]

Fine silver is cast into marketable bars, rods, and granules by using gas- or oil-fired furnaces and gas or electric crucible furnaces. The molten metal is cast into bars in iron molds. Reducing conditions are used during melting to prevent the absorption of oxygen by molten silver, which leads to spitting on solidification (see Section 2.3), and hence to an uneven surface on the

Figure 27. Phase diagrams of binary silver alloys: Ag – Pb

Figure 28. Phase diagrams of binary silver alloys: Ag – Pd

solid metal. In early days, the oxygen in solution in the silver was removed by stirring the melt with poles of green birch wood. Today, graphite, phosphorus, or lithium is added, or melting operations are carried out in a reducing atmosphere. Granules of fine silver are produced by pouring a thin stream of molten silver into water.

The melting of silver alloys is now carried out almost exclusively in induction furnaces. These cause a stirring effect during the melting process, which ensures thorough mixing of components. Also, the operation can readily be carried out under a protective gas to prevent uptake of oxygen. Melting under vacuum is not feasible because of the relatively high vapor pressure of silver. When molten silver alloys solidify, nonhomogeneous layer crystals nearly always form on a microscopic scale, but they can be homogenized by heat treatment. With large castings, which require a long time for cooling, liquation effects can lead to irreversible variations in composition. This causes problems in processing cast bars and billets to form sheet or wire, because the tolerances for the alloy compositions in these applications are very tight.

Figure 29. Phase diagrams of binary silver alloys: Ag – Pt

Figure 30. Phase diagrams of binary silver alloys: Ag – Rh

Silver alloys can also be shaped by continuous casting (Fig. 36). Simple profiles, as well as complex, semifinished profiles closely approximating the final cross section required (near net shape), can be produced directly from the melt. This is a major advantage because costly reprocessing is minimized. The continuous production sequence of continuous casting guarantees consistent product quality, while control of secondary cooling can prevent undesirable segregation effects. Horizontal continuous casting is used for high throughputs and large cross sections. Vertical casting plants are preferred for high-quality material and kilogram quantities.

The investment costs for continuous casting plants are very high; however, the advantages of the process have given it a dominant position in silver production technology.

Silver and silver alloys, whether produced by ingot mold or continuous casting, are converted into rods, wires, and profiles in extrusion presses. Intermediate heating is necessary, depending on the material and the extent of forming. Extrusion presses often produce directly salable end products (e.g., silver solder wire). Oth-

Figure 31. Phase diagrams of binary silver alloys: Ag – Ru

Figure 32. Phase diagrams of binary silver alloys: Ag – Si

erwise, further forming processes are required, which can include rolling, drawing, hammering, bending, pressing, stamping, forging, and weaving into gauzes. Cutting processes can also be used, including turning, milling, planing, simple engraving, and engraving with a rose engine.

For smaller items such as jewelry or fittings for chemical equipment, investment casting can be used. Usually, centrifugal casting is preferred, the molds being produced by the lost wax process. Problems of homogeneity and segregation do not usually arise here.

Thermal treatment processes not only homogenize the castings, but also restore the structure (texture) of the metal that is responsible for its hardness. Intermediate heating between forming stages must generally be carried out in nonoxidizing atmospheres for silver – copper alloys. Protective gases used include hydrogen, nitrogen, carbon monoxide, argon, or cracked gas. If silver alloys come in contact with atmospheric oxygen during thermal treatment, coatings of base-metal oxides are formed. These scale layers can be removed by pickling. If the scale con-

Figure 33. Phase diagrams of binary silver alloys: Ag – Sn

Figure 34. Phase diagrams of binary silver alloys: Ag – Ti

sists mainly of copper oxide, it can effectively be removed with 10 % sulfuric acid at 70 °C.

Sintering techniques are limited to composite silver materials.

Tula silver is silver that has been decorated by the so-called niello technique, in which a black, sulfur-containing Ag – Cu – Pb alloy is melted into an engraved design.

Silver alloys may be bonded together by the usual soldering, welding, and adhesive processes.

10. Uses [120]

10.1. Coins [1, 2, 6, 121]

The amount of coinage in circulation has undergone with fluctuations throughout the course of history. The interchange between the monetary and functional use of silver has often been influenced by the political situation. In times of war, silver was monetized to a greater extent to pay the costs, and when prosperity was restored, the metal returned to private possession in the form of silver articles. Since the growth of the industrial demand for silver, it has become de-

Figure 35. Phase diagrams of binary silver alloys: Ag – Zn

monetized. Nevertheless, large quantities of silver coins, withdrawn from circulation, are still used as national reserves. Even today, in some countries, small coins and banknotes are backed up by actual quantities of silver. In Germany, the circulation of silver coins reached a high point in 1880 before the introduction of paper money (see Table 10).

In ancient times, silver coins were minted from refined silver (980/1000 to 990/1000), especially in Athens and Rome. The coins of the Middle Ages usually have a fineness between 900/1000 and 990/1000. The actual value of these coins matched their face value. However, in periods of coinage debasement, so-called token coins also existed, whose metal value was less than their face value, and in which the silver content was reduced to ca. 500/1000. In the 1900s, token coins were minted generally. The silver content fluctuates between 945/1000 and 400/1000. Some silver coins are listed in Table 10.

The technique of minting silver coins has undergone many changes over time. At first, silver coins were produced partly by casting and partly by means of a hammered die. Various designs of press were then used. Today, rods or ingots are first produced by continuous casting. The ingots or rods are rolled to form plates of the exact thickness for coinage production. These plates are then heat treated in a protective gas (high-silver alloys) or in air (low-silver alloys) to remove the effects of cold work hardening. Blanks are then cut or punched out of the plates. At lower silver contents (< 800/1000) blanks are then blanched (whitened) by dipping in dilute sulfuric acid to dissolve both the thin oxide layer and the copper near the surface of the metal. This gives a lighter surface color and a pure silver appearance. After being washed, the coin blanks are dried in centrifuges, the edges are knurled in milling or crimping machines, and the edge lettering is added, this is followed by minting in a coining press or coining machine. Modern minting machines produce 8000 coins per hour.

10.2. Jewelry [18, 19, 122]

In earlier times, the manufacture of silver articles for jewelry and general use was the main outlet for silver, apart from coinage manufacture, and it is still very important. The category includes table silver such as cutlery, jugs, dishes, plates, and cups, as well as goblets, trophies, cases, church silverware, vases, lamps, and articles of jewelry such as necklaces, bracelets, broaches, pendants, and rings. Silver is also used in the fabrication of musical instruments, especially flutes. Apart from its investment and display aspects, the bactericidal action of silver has always been an important aspect of the purchase and use of silver tableware articles (see Section 13.2).

Today, silver – copper alloys with finenesses of 925/1000, 835/1000, and 800/1000 are used in

all forms of jewelry because of their favorable properties for both manufacture and use [123, 124]. Whereas fineness is now marked in thousandths, the earlier system used "Lot" units (sixteenth parts; see Table 11). Fineness was also expressed in the Russian solotnik system.

The standard materials, Ag 925, Ag 835, and Ag 800 are supplied in the form of sheets, bands, wires, rods, tubes, and profiles. The industrial process of alloy production in a vacuum oven followed by casting and cold forming has now been replaced almost entirely by continuous casting. The quality of the alloys has thereby been improved, especially with respect to homogeneity, shrinkage, gas cavities, and formability.

Tarnishing of silver is a result of the formation of silver sulfide caused by the action of hydrogen sulfide and its organic or inorganic derivatives. In the tarnishing of silver alloys, copper corrosion is significant, especially the distribution of copper in the structure. Incorporation of gold, platinum, or palladium into the alloy improves tarnish resistance but is expensive. Base-metal alloy components such as zinc, cadmium, silicon, and germanium change the color and luster without preventing tarnishing completely. Electrolytic pure silver coatings are more resistant to tarnishing than the usual silver – copper alloys. Rhodium coatings, which were sometimes used in the past, are expensive and alter the appearance, albeit only slightly. Colorless coatings (e.g., lacquers) also spoil the appearance of the silver surface.

Dipping baths for removing the tarnished layer reduce silver sulfide to fine silver, which washes off without affecting appearance. Pastes are also used that contain extremely fine abrasives and reducing agents such as sodium dithionite. Surface-active additives, usually silicone based, give some extended protection. The tarnishing of cutlery, in particular, can be prevented by wrapping it in a cloth impregnated with finely divided elemental silver. These cloths absorb sulfidic compounds from the air so that they cannot react with the compact metal surface. The most effective method of treatment, however, is still the laborious process of cleaning with a paste, which removes not only the surface layer of silver sulfide but also small surface imperfections, giving a smooth polish and restoring the original luster and warm color of the silver.

Coloring. The only important coloring processes are blanching with sulfuric acid and forming oxidized silver, which is a type of partial tarnishing.

10.3. Medicine [1,2,18,19,23,24]

Silver compounds are used only sporadically in internal medical therapy, although they were more widely used in earlier times for the treatment of epilepsy and gastric ulcers. Today, their main use is for their bactericidal action on certain pathogens. Here, they behave similarly to mercury compounds but are less toxic. Several complex compounds of silver that can be absorbed through the mucous membranes are used, mainly for disinfection of the throat. The use of very dilute solutions of silver nitrate was for a long time a legally prescribed prophylactic treatment against possible streptococcal infection of the mucous membrane of the eyes of newborn babies in Germany. Silver nitrate is a component of Fisan silver powder for the treatment of surface wounds. The local caustic effect of silver nitrate can be used to destroy proliferating tissue. A protective layer of silver chloride and silver albuminate is formed by reaction with the skin, limiting the extent of the caustic effect, which is also associated with an antiseptic and astringent action. Sulfadiazine silver(I) [AgSD, 2-sulfanilamidopyrimidine silver(I)]

is used as a bacteriostatic compound in the treatment of life-threatening burns [120, 125].

Colloidal silver sols have similar bactericidal properties due to the oligodynamic action of silver (see Section 13.2). They are used in the form of stabilized solutions for disinfecting wounds, as are colloidal sols of sparingly soluble silver compounds.

Silver and silver alloys have long been used as bone replacements, mainly in cranial surgery. Also, silver wire is used in suturing connective tissue, and fine silver gauze is used as an implant. Here, too, the oligodynamic properties of silver

are beneficial. It was once common to place silver foil or even silver coins on wounds for the same reason.

10.4. Dentistry [18,23,24,58]

Silver – tin amalgams are used in dentistry to fill tooth cavities (see also → Dental Materials, Chap. 2.2.2.). The preferred alloys contain ≥40 % silver, ≤32 % tin, ≤30 % copper, ≤2 % zinc, and ≤3 % mercury. They are produced initially in the form of cast blocks, which are then powdered by machining or converted to small spheroidal particles by atomization. The dentist mixes this alloy powder with an approximately equal weight of mercury to give a stiff paste. This paste is condensed carefully into the tooth cavity, the liquid mercury acting as filling matrix and lubricant. Hardening is completed after a few hours and is accompanied by a small volume increase. In the older types of alloy, the important metallic phases present before hardening were Ag_3Sn, Sn, and Hg. During hardening, the Ag_3Sn γ-phase, which is the main component of the powdered amalgam, reacts with mercury to form a solid phase Ag_3Hg_4 (γ_1), and a Sn – Hg solid solution Sn_8Hg (γ_2). The reactions are incomplete because the amount of mercury is insufficient. Some Ag_3Sn (γ) always remains in excess.

Because of the presence of the base metal tin, the γ_2-phase is the weakest component of a filling with respect to both corrosion and mechanical properties. Formation of the γ_2-phase can be suppressed by increasing the copper content. Such formulations are known as non-gamma-2 amalgams. Despite advances in polymer-based filling materials whose color matches that of the tooth, non-gamma-2 amalgams have continued to fulfill an important function in the treatment to rear teeth where biting forces are higher.

Silver-containing alloys are also used in dental prostheses (→ Dental Materials, Chap. 2.3.). Gold-colored (gold-based) noble-metal alloys may contain 10 – 15 % silver, some white noble-metal alloys based on silver – palladium contain up to 65 % silver.

10.5. Coatings [18,19,24,126,127]

10.5.1. Silver Electroplating [128,129]

Electrolytic deposition is the most important process for producing silver coatings. The electrolytes used are alkaline baths of potassium dicyanoargentate(I) containing an excess of potassium cyanide, with potassium carbonate as the conducting salt (→ Electrochemical and Chemical Deposition, Chap. 8.17.). Soluble pure silver anodes replace the metal deposited from the electrolyte onto the cathode. For plating articles in daily use, the preferred substrate is German silver (45 – 70 % Cu, 5 – 30 % Ni, 8 – 45 % Zn), which combines good mechanical properties with good adhesion to the silver coating. Copper and nickel can also be electroplated directly. A thin initial silver coating (strike), produced in a special bath, often increases adhesion considerably. When electroplating iron, an intermediate coating of copper or nickel is neces-

sary. Articles made of plastic (mainly acrylonitrile – butadiene – styrene and polyurethane) or ceramic can be electroplated with silver if the surface is first provided with an electrically conducting coating by the electroless deposition of copper or nickel.

The luster of silver coatings can be improved by additions of xanthates or thiourea to the plating bath. Their hardness can be influenced by doping the bath with antimony, bismuth, arsenic, selenium, or lead [133]. Highly abrasion-resistant coatings, so-called dispersion coatings, are produced by dispersing ceramic materials in the electrolyte during deposition.

Coatings having different thicknesses at different parts of a workpiece can be produced by using special anodes that match the geometric shape of the workpiece and by controlling the electric field in the electrolyte with the aid of masks. This technique can be used, for example, to produce thicker deposits on cutlery at places where increased wear is expected.

Silver electroplating is used mainly in the cutlery, jewelry, and electronics industries. In total, considerably more silver is used in the manufacture of electroplated cutlery than for solid silver cutlery. The potassium dicyanoargentate(I) used in the process is the silver compound produced in greatest quantity after silver nitrate and silver(I) oxide. The quality of silver plating on cutlery is quoted in grams of silver per dozen table settings consisting of three items per setting. For the usual qualities, 60, 90, or 100 minimum coating thicknesses are specified (e.g., 36 μm for a 90-g silver plating) [127, 134]. For jewelry, coatings are considerably thinner (e.g., 5 – 10 μm). In electronics, thicknesses of a few micrometers are often sufficient.

The deposition of silver alloys usually leads to heterogeneous coatings with inferior technical properties, although significant improvements have been obtained using gold-colored Au – Cu – Ag alloy coatings, in which silver is used in place of cadmium to lighten the color [58].

Silver electroplating is carried out in batch or continuous equipment and by barrel plating. Wire-plating plants are also operated. In some cases, partial silver plating is carried out by brush plating, in which the anode and cathode are linked by a pad soaked in electrolyte.

In bulk production, continuous-flow plating plants are widely used, especially in the production of electronic components [58]. As with electroforming, their importance for gold is greater than for silver.

The need for much higher rates of electrodeposition became evident in the early 1970s when the demand for plated electronic components increased rapidly. For high-speed plating a special silver electrolyte was developed containing no free cyanide. Silver is still introduced as $K[Ag(CN)_2]$, and insoluble anodes are used. Current densities are generally between 35 and 350 A/dm^2 [130].

All attempts to develop non-cyanide silver-plating solutions have failed to provide a process that is as stable and robust as the traditional one.

10.5.2. Silver Plating by Chemical Reactions [2, 18, 126]

Deposition of silver from aqueous solutions of silver salts onto workpieces of base metals normally leads to silver coatings of inadequate quality. However, by using a solution of $K[Ag(CN)_2]$, a fairly adherent – although very thin (<1 μm) and somewhat porous%sp12;– coating can be deposited on copper by this simple method. The process is known as cementation plating.

The deposition of silver can be accelerated by contacting the metal to be plated with aluminum or zinc (contact silver plating). This plating process gives thicker, pore-free silver coatings. Contact silver plating is carried out in hot cyanide electrolytes. It is very economical for mass-produced articles, but has declined in importance.

Instead of base metals, chemical reducing agents can be added to the cyanide electrolytes [e.g., sodium hypophosphite (NaH_2PO_2), sodium borohydride, hydroquinone, or hydrazine hydrate]. The cementation reaction with the substrate metal also takes place to some extent. This plating process is improved by the addition of complexing agents such as ethylenediaminetetraacetic acid. Plastics and ceramics can also be plated by an electroless method after activating pretreatment with tin(II) chloride and palladium (II) chloride solution.

Silvering of glass, mainly for mirrors, Christmas tree decorations, and vacuum flasks, is performed with an ammoniacal silver nitrate solution to which a solution of formaldehyde and sodium hydroxide is added as reducing agent [2, 135]. Silver is deposited on the surface of the glass, usually on warming. This reduction reaction is also used in spray silvering, in which the two solutions are applied through the separate nozzles of a spray gun.

Friction plating consists of rubbing a workpiece with a moist mixture of very fine silver powder, silver chloride, and a reducing agent. This process was formerly used for silvering clock faces.

Post treatment. Silver will tarnish in time due to surface sulfide formation. Treating the silver cathodically in an alkaline chromate solution will prevent tarnishing for some time. Ornamental items can be coated with a clear lacquer. Epoxy and acrylic materials applied electrophoretically are excellent. However, these films cannot be used on components whose surface performs an electrical function.

10.5.3. Mechanical and Thermomechanical Plating [18, 19]

Mechanical plating processes are often used to produce thick silver coatings, mainly for chemical apparatus, heavy-current contacts, and coating composite semifinished products.

In roll cladding, silver is bonded to the base metal at a very thin boundary region where the two metallic crystal lattices become interlocked. Cold and hot roll cladding can be carried out.

In solder plating, a silver brazing alloy is introduced between the two surfaces to be joined, and the melting point is exceeded by a definite amount on compressing the heated metal sheets. In some systems (e.g., silver – copper), a solder-like bond is produced if the melting point of the eutectic mixture of the two metals is exceeded in the boundary region. This process is known as hot press welding or eutectic welding.

Other plating processes that can be used with silver include cold press welding, atomic hydrogen arc welding, and explosive cladding.

10.5.4. Physical Vapor Deposition.

Thin silver coatings on various substrates are produced by vacuum evaporation, by cathodic sputtering, or by ion plating. These are used in microelectronics and for decoration purposes.

A fast growing application of sputtered silver films is heat mirrors.

Thin layers of silver with thickness below $\sim 0.012\,\mu m$ are transparent for optical light waves in the visible range (380 – 780 nm) but reflect in the long-wavelength region. These layers, deposited on architectural window glasses by sputtering, reduce energy losses caused by outgoing heat radiation. Additional thin, transparent, and color-neutral oxide coatings serve as antireflection layers and to improve adhesion, corrosion resistance, and mechanical stability. Special sputtering equipment and target material conditions have been developed for large-scale batch type and continuous processing of coherent layers of homogeneous thickness [131, 132].

Figure 37. Silver pressure-contact plates for powder semiconductor devices [19, p. 487]

10.5.5. Firing Processes [18]

Ceramic articles (e.g., porcelain tableware and industrial porcelain components) and glass can be silvered by melting pasty silver-containing preparations. The resulting coatings can be soldered, polished if they are sufficientyl thick (1 – 10 μm), or used as a basis for further electroplating. The pastes consist of suspensions of very fine silver powder or organic silver compounds with powdered glass in essential oils. Heating must be carried out with addition of air

Figure 38. Silicon solar-cell with printed silver contact paths [19, p. 482]
A) polycrystalline; B) Single-crystal substrate (courtesy Nukem-Solartechnik Alzenau)

to burn off the organic components completely, preferably at 550 – 800 °C. Electronic components are often selectively silver plated by screen printing. In the mass production of glasses and porcelain tableware, decorative patterns are applied by transfer processes. Very thin layers, especially on glass, ceramic, or porcelain substrates, are also made by thermal decomposition of complex organo silver compounds (resinates) both for decoration and for microelectronic circuitry.

10.6. Electronics and Electrical Technology

10.6.1. Electronics

Silver is, due to its high electrical conductivity, the preferred conductor and electrode material. Electronic applications comprise vacuum electron tubes, active and passive semiconductor devices, electronic circuits, and components and materials needed for their production. It is used in bulk form (e.g., contact plates of rectifier and thyristor devices, (Fig. 37), as surface layers and contact pads of semiconductor chips, on silicon and gallium arsenide solar cells (Fig. 38), on lead frames (Fig. 39), packages (Fig. 40), printed circuits (Fig. 41), thik and thin-film circuits (Figs. 42, 43), capacitors (Fig. 44), and automotive windshields. Silver and silver alloys in powder form are constituents of paste preparations used for the production of conductor layers and electrodes in hybrid thick-film circuits, ceramic capacitors, and other active and passive ceramic electronic components. Silver alloys in various compositions find application as soft solders and brazes. The main applications are presented in Table 12.

Figure 39. Lead frames and systems carrier with galvanic deposited contact layers of silver (Degussa Präzisionstechnik, Niefern)

The surface lay ers – especially for printed circuits, lead frames, and component assembly are made by galvanizing, by sputtering (e.g., for thin-film circuits), or by using powder-containing paste preparations, which are applied by screen printing and firing (thick-film circuits and electrode layers of capacitors). Typical compositions of metallizing preparations are given in

Figure 40. Ceramic packages for semiconductor power devices (courtesy Frialith, Friedrichsfeld)

Table 12. Applications of silver in electronics, [189, p. 557]

Form	Applications
Bulk	pressure-contact plates for power semiconductor devices
Bimetal	plug-in contacts, pressure-contact and soldered base plates
Surface coat	
electroplated	printed circuits boards (PCB) for high frequencies, system carrier, Mo and W base-plates, lead frames
sputtered or evaporated	contact surfaces on Si diodes lead frames
pastes, lacquers	conductor pastes for thick film circuits, potentiometer, capacitors, contact foils, screening, glass solders
solder connection	tubes, package joining components, soft solders in semiconductor devices, die-attach

Table 13. Metallizing lacquers contain silver-powder suspensions in organic lacquers. They are applied by brushing, printing, or dipping and are dried on air at moderate temperatures up to 250 °C. They are used for the production of potentiometers, Ta capacitors, flexible circuits, membrane switches, electrical shielding and other electronic devices on substrates such as plastics, glass, wood, paper or similar materials which cannot withstand temperatures above about 250 °C [182].

Multilayer capacitors are built up from alternating layers of ceramic and conductive material, usually consisting of Ag – Pd alloys or pure Pd. The layers are terminated at each end of the chip by silver coating (Fig. 45). They are produced by alternately applying layers of ceramic and of conductor pastes, then laminating together ("wet-in-wet" process), and firing in a single operation. The paste preparations are made from special powder grades of pure silver, palladium, or silver – palladium alloys with glass frits and organic binders. Table 14 lists some characteristic properties of typical powder grades.

Figure 41. Multilayer printed circuit board with silver conductor network and gold contact pads for assembling with active and passive devices by surface mount technic (Schoeller Electronic, Wetter)

High-purity silver powder, as required for metallizing and electrode pastes in electronics, is produced by a two-step process:

$$2\,AgNO_3 + Na_2CO_3 \longrightarrow Ag_2CO_3 + 2\,NaNO_3$$

$$Ag_2CO_3 + HCHO \longrightarrow 2\,Ag + 2\,CO_2 + H_2$$

This process allows the alkali metal to be removed by washing before the silver carbonate is reduced with formaldehyde.

The powders are characterized by particle shape, particle size, particle size distribution, BET specific surface area [183], and tap density

(ASTM 527-85 [184]). These parameters influence important production parameters such as paste rheology, sinter temperature, and density of coats after firing. Different powder production technologies lead to characteristic properties. The most common method is chemical reduction, predominantly in aqueous solution. Addition of protective colloids and compounds that promote wetting, enable the control of particle size and prevent particle conglomeration during powder deposition, Particle sizes, which also de-

pend on the process conditions are usually in the range between 0.5 and 20 µm (Fig. 46 [185]).

Melt atomization is used for the production of silver and silver alloy powders for soft-solder and brazing pastes (Fig. 47 [185]). This is performed by mechanical dispersion or by spraying through nozzles and quenching the particles in water. High-purity spherical powders with good flow properties are formed in an inert-gas atmosphere.

Lamellar powders (flakes) are obtained by milling the deposited powders in liquid suspensions. The plate thicknesses range from 0.1 to 1 µm. The flakes are used as pigments in conductive paints and in conductive adhesives, the face contact between the flat grains leading to increased conductivity (Fig. 48 [185]).

Figure 44. Plate and tube capacitors, metallized with silver preparations (Demetron)

Nanocrystalline powders with particle sizes in the range of 10 to 1000 nm and also colloidal dispersions are produced by condensation of silver vapor formed by electron beam evaporation on cool surfaces, by generating an electric arc between two silver electrodes immersed in suitable liquids, or by chemical reduction in the presence of special protective colloids. Ultrafine silver powder in an organic binder forms films with very stable electrical resistance; these are used as sensors to determine the position of magnetic tapes [186, p. 628].

Figure 45. Multilayer ceramic capacitor (MLCC); cross section, with silver-palladium electrode layers and silver contact edge (Demetron)

Silver-based binary, ternary, and quaternary solder alloys are used for the mechanical and electrical connection of semiconductor materials with metal or ceramic components (packages, heat sinks, etc.). Addition of silver to lead – tin soft solder alloys increases the mechanical strength, improves the wetting and flow properties in the molten state, and reduces the leaching of the silver surfaces during the soldering processes. The soldering processes in electronic device and package production are predominantly carried out without flux under protective atmospheres. The solders are applied in the form of wires, foils, pastes (in preparations with an

organic binder), or solder preforms (spheres, disks, or special shapes). The melting temperature range of soft solder alloys (based on lead, tin, or indium) is ca. 159 – 400 °C, and that of the brazing alloys (consisting of different compositions in the systems Ag – Cu and Ag – Cu – Pd) ca. 600 °C and above (Table 15). The ternary alloy SnSb10Ag25 has an extended melting range and higher tensile strength than the common soft solders due to the presence of low-melting phases together with hard, high-melting intermetallic compounds [187]. It is used for the die attach (connection of the semiconductor chip with the substrate) in devices which have to withstand mechanical stresses caused by temperature cycling (e.g., power devices and devices in automotive electronics).

10.6.2. Electrical Technology [2, 18, 19, 23, 24, 137]

Silver has the highest electrical and thermal conductivity of all metals, and as a precious metal it is largely corrosion-resistant. In particular, because no oxides are formed in air, silver gives extremely low electrical resistance at contact points in electrical switching devices.

Only silver sulfide, which is formed in sulfur-containing atmospheres, can hinder the flow of electric current at low contact forces, so the application of silver is concentrated in power

switching devices with their relatively high contact forces. Beside pure silver, silver – copper and silver – nickel alloys, especially the composite metals Ag – Ni, Ag – W, Ag – Mo, and the composite materials Ag – CdO, Ag – SnO_2, Ag – graphite, and Ag – WC are used (see Table 16).

The composite materials are usually produced from mixtures of the components by powder metallurgy or they can sometimes be obtained by coprecipitation followed by thermal treatment. For example, the composite system Ag – CdO can be produced by internal oxidation of the cadmium in an Ag – Cd alloy. In the case of molybdenum and tungsten, silver can be absorbed into a matrix of these refractory metals.

The choice of a specific contact material is determined by the stresses to which the contacts are subjected during making, carrying current, and current breaking.

- During making in an electric switch, the contacts bounce, and mechanical wear, transfer of the contact material from one contact to other, and arc erosion occur. There is a risk that the contacts will weld at the areas melted by the arc.
- When carrying current through closed contacts in switches and connectors, the contact resistance influences the voltage drop as well as the temperature rise and the tendency to static welding of the contacts.
- During breaking the contacts are again subjected to mechanical wear, material transfer, and arc erosion. The contact material also has an effect on arc movement and arc extinction.

While for switching currents up to 10 A the requirements can still be fulfilled by alloys like fine grain silver (AgNi 0.15) and hard silver (AgCu with 3 or 10 %), it is necessary to use composite materials for higher currents. The components, which form sintered, impregnated, or internally oxidized composite materials with the silver, are dependent on the type of switching device, its construction and the amount of current which the device must deal with under the most severe conditions. An optimum contact and switching behavior can be attached by selection of the composition, the method of manufacture, and the structure of the material for each switching device.

In Figure 49 a qualitative evaluation is given for the most important groups of materials for their contact and switching behavior by means of a simplified model. There is no optimum group materials. AgC guarantees the highest resistance to welding, but a major disadvantage is the very high erosion. AgW materials behave in the opposite way. Silver – metal oxides show predominantly positive properties and are used in nearly all switch gears with a switched current in the range of 100 – 5000 A. Because of the not completely satisfactory welding behavior above 5000 A, the materials of this group can only be used in protective and safety switches to a limited extent. AgCdO, the material used most frequently up to a few years ago, is being increasingly replaced by the more environmentally friendly $AgSnO_2$. For switching devices with a maximum switched current of 100 A, AgNi has been found appropriate, and it can be worked very easily. The contact and switching behavior of fine-grain silver and hard silver are comparable to those of pure silver, but with significantly less mechanical wear.

The areas of application for the different groups of materials are shown in Figure 50. For domestic switches, AgNi10 is the main material, and in simple switching devices in domestic installations, AgCu. Only when in both applications the contacts bounce is strong it is necessary to use silver – metal oxides like AgCdO or $AgSnO_2$. Protective switches, in which the contacts should never weld for safety reasons, have mainly AgC contacts in MCCBs and RCDs combined with Cu, and in MCBs with AgNi (20 – 40 % Ni). In auxiliary switches, such as control switches, which may only switch up to 100 A max., AgNi10 has proved best. If the switching currents are above 100 A, as in disconnectors, circuit breakers, and starters, mainly in the form of large contactors, silver – metal oxides are predominant. Here the AgCdO used up to now will be completely replaced by the newly developed material $AgSnO_2$ with 10 or 12 % SnO_2.

There are also a number of other switching devices in which silver-based materials are used for the contacts, for instance, railway switching devices or in switches and relays for motor vehicles. In electric fuses, which are also included in switching devices, silver elements are used when a high precision of the switching characteristic and good resistance to aging are required.

For fuses, silver-coated copper wires are preferred because they do not oxidize even after

Table 16. Silver-based materials for electrical contacts

prolonged heating, and their resistance therefore remains constant. So-called superquick-acting fuses for protecting semiconductor components are made of silver wires with a defined reduction in cross section at certain points.

Silver compounds are used in the construction of electric batteries (see → Batteries, Chap. 6.1.3.2.). Silver(I) oxide is used in button cells for general electronic equipment. Silver(II) oxide, which has a higher capacity owing to divalent silver, is increasingly being used in button cells in both space and military applications. The AgCl – Zn combination is employed in emergency batteries used at sea. These start to operate automatically on contact with seawater.

The high solubility of oxygen in silver and its inertness against high-temperature reaction with ceramic oxides is used for the production of superconducting wires and tapes in single and in multifilament structure by the powder in tube technology (PIT) [188]. The high-temperature superconductors (HTSC) are based on ceramic oxides (BSCCO = $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ with $n = 1$, 2, 3; for $n = 3$: Bi-2223). Precursor ceramic oxide powders are filled into silver tubes, which are rolled and then drawn to the final diameter. On subsequent heating in air, oxygen penetrates through the silver tube and reacts with the

precursor powders to form the superconducting compounds.

10.7. Brazing Alloys [2, 18], [19, pp. 551 – 561][58, 142–146], [190, vol. 2, pp. 675 – 678], [191]

Silver-containing brazing alloys (→ Soldering and Brazing) are widely used for joining industrial metallic materials, mainly those based on copper, nickel, and cobalt alloys; tool steels; and precious metals. The main applications include brazing of construction materials, electronic components, silverware, carbide tips onto cutting tools, wear-resistant tungsten or molybdenum tips on copper alloy resistance welding electrodes, and high-temperature-resistant machine parts.

The compositions are mainly based on silver – copper alloys and contain, depending of the application type, additional amounts of one or

more of the elements Zn, Sn, Cd, Pd, Mn, and P. Table 17 gives a general survey of the most important types. Silver – manganese alloys are especially suited for soldering hard-metal and refractory surfaces (molybdenum, tungsten, tantalum). Additions of nickel or cobalt increase the strength of the bond. Ag – Pd – Cu alloys are the preferred fillers for high-temperature applications (gas turbines, supersonic aircraft, nuclear technology). For health and safety reasons, the cadmium in these alloys is being replaced as much as possible by other metals such as tin or indium.

The advantage of silver-based brazing alloys compared to those containing only base metals such as brass or German silver consists of improved workability and improved oxidation resistance during brazing. Silver-containing brazing alloys give stronger joints than brass alloys.

Compared to base metal brazing alloys like brass or German silver, the silver-based brazing alloys are more malleable. They can be drawn or rolled with high reduction between annealing steps. Silver-containing brazing alloys are mainly supplied as wires, sheets, rods, and shaped pieces of many kinds. Special preforms made of laminates of two silver – manganese outer layers on copper sheet are used to reduce mechanical stresses when materials with large differences in thermal expansion are to be joined, e.g., hard metal on steel.

Brazing alloys usually require a flux, protective gas, or vacuum. Exceptions are phosphorus-containing copper – silver brazes, which are self-fluxing on copper, silver, and tin bronze surfaces. They find application in electrical engineering and in cryotechnology, where the connections have to withstand temperature differences extending over wide ranges down to − 50 °C. For joining ceramic to metal, the ceramic surface must first be metallized with an Mo – Mn preparation (coating with pastes, drying, and firing) and then galvanically plated with nickel. Direct brazing of ceramics can be carried out without previous metallization by using the so-called active silver-brazing alloys (see Table 18). They contain 2 – 4 % titanium or zirconium. Bonding is performed by reaction of the refractory metal with the ceramic, forming an adherent bond layer.

Developments have been in the direction of flexible brazing alloys coated with flux and brazing alloys in paste form. Both of these extend the efficient use of mechanized brazing equipment, reducing the time required for brazing in mass production work. The electrical conductivity of the different silver brazing alloys depends on the silver content and ranges between 10 and 80 % IACS.

High-purity silver – copper alloys (preferably the eutectic alloy Ag – Cu28, *Mp* 779 °C, electrical conductivity ca. 77 % IACS) are needed for joining under vacuum, protective gases, or reducing gas atmospheres. The minimum purity of the components is 99.99 %. They must be free of metallic and nonmetallic constituents that have high vapor pressures at the soldering temperature (e.g., zinc, cadmium, arsenic). Palladium additions increase the mechanical strength. These alloys are predominantly applied for brazing of metallized ceramics with vacuum-tube metals and molybdenum, tungsten, zirconium, and beryllium.

The use of silver-based brazing alloys in high-tech applications is increasing. These include microelectronics, power electronics, energy technology, and aircraft and space technology. Difficult bonding problems (e.g., with titanium alloys, dispersion-hardened alloys, and hard metals) can be solved by brazing techniques, even when high strength and temperature resistance are required. This is also true of ceramic components (Si_3N_4, ZrO_2, etc.) and diamond.

Silver is also used in solders, but in lower concentration. For example, the solder L-SnAg 5 contains 3.5 % Ag and melts at 221 °C. Tin- and lead-containing solder alloys find extensive use in the production of electronic and semiconductor devices (see Section 10.6.1).

10.8. Chemical Equipment [18, 147–150]

Silver is a very useful, although expensive, material of construction in the chemical industry, having good chemical resistance, high thermal conductivity, and good mechanical and working properties.

In the chemical laboratory, silver crucibles are used mainly for alkaline fusion [149]. The presence of ca. 0.15 % nickel in the alloy prevents recrystallization on heating to red heat, which can lead to a coarse and brittle metal struc-

CS 2				4	4	92	320 – 325	850 – 950

ture. In preparative fluorine chemistry, silver, as well as copper, is often used for equipment parts [87].

Silver-plated articles are used in chemical process technology. These include vessels, autoclaves, pipework, heat exchangers, and sometimes small fittings. Equipment made of massive silver is uncommon, but is used for concentrating strongly alkaline solutions, for solutions of hydrochloric acid, and for fruit juices. For cost reasons, the load-bearing material is usually copper or steel, with silver cladding a few millimeters thick. In most cases, the two sheets of metal are bonded together by a combination of mechanical treatment and fusion, and the equipment is fabricated from the resulting composite. Alternatively, silver cladding can be applied to a finished steel construction. Vessels to withstand several hundred degrees Celsius are sometimes provided with a loosely fitting silver lining. Although this does not give optimum heat transfer, the difference in the expansion of the two metals does not constitute a risk of damage to the vessel. Vessels can also be plated internally by electrodeposition. Coatings >50 µm thick are generally nonporous.

Silver fittings are often machined from castings. In chemical equipment, the metal can be pure silver, fine-grained silver, or oxide dispersion-hardened silver, which has better high-temperature strength.

Filter elements of sintered spheroidal silver powder are used in the food industry, principally in fruit presses. Membranes for bursting disks to protect equipment against excess pressure can be made of 0.1 – 0.5-mm-thick silver disks. They can be used in the range of 0.1 – 40 MPa at ≤120 °C. Small tubes of palladium or Pd 77 Ag 23 are used in diffusion cells for the production of pure hydrogen. Pure silver and gold – silver alloys in wire or ring form are used in the manufacture of sealing materials for oxygen compressors and ultrahigh-vacuum equipment.

10.9. Catalysts [150]

Metallic silver is an excellent oxidation catalyst. Without doubt, the specific activation of oxygen at the metallic silver surface, forming an intermediate state, plays a part in catalytic activity. Usually, fairly coarse-grained metallic silver is used, because a finely divided product with very large specific surface area would in many cases cause total oxidation of the organic substance to carbon dioxide and water.

Ethylene oxide is produced by direct oxidation of ethylene on silver catalysts at 230 – 270 °C (→ Ethylene Oxide, Chap. 4.) [151]. These are supported on α-Al_2O_3 or silicates and have a silver content of ca. 15 %. The specific surface area of the metal is fairly low. These catalysts usually have a lifetime of several years.

Skeletal silver catalysts have also been proposed for the oxidation of ethylene to ethylene oxide [152, 153]. They are best prepared by decomposing the alloy Ag – Ca with water. However, they have not yet been used industrially.

Catalytic dehydrogenation of methanol to formaldehyde (→ Formaldehyde, Chap. 4.1.) is carried out at 600 – 720 °C over silver gauze or crystals. Catalytic oxidative dehydrogenation of isopropanol to acetone also takes place on silver catalysts. In gas-phase reactions over silver catalysts, glyoxal is produced from glycol, and acetaldehyde from ethanol. Likewise, organic amines can be dehydrated to nitriles on silver catalysts.

10.10. Photography [154] (→ Photography)

Classical silver halide photography has been subject to increasing competition from digital photography in the last few years. Nevertheless, silver halide photography will keep a considerable market share, especially in amateur photography, for the next decade.

In black-and-white photography, the light-sensitive emulsion coating consists of a gelatin layer in which silver halide crystals are suspended (two gelatin layers in X-ray films). The bromide ion is used more than chloride or iodide. The method of precipitation determines the structure of the particles in the silver halide mixture, and hence the photographic properties of the emulsion. The distribution of individual halides in the emulsion particles, the grain size, and the grain shape can be varied over a wide range, as can the bromide : chloride : iodide ratio. Properties are also influenced by physical and chemical maturing processes. Addition of special noble metal compounds enforce light sensitivity, developing properties and tuning. In the development of black-and-white film and paper, the grains that come in contact with photons are reduced by chemicals to elemental silver, to produce the black color. Silver halide grains that have not come in contact with light do not react and are dissolved by sodium thiosulfate during fixing.

In color photography, three primary colors, corresponding to the sensitivity of the human eye, must be produced. For each of the three colors, a photographically sensitive layer is required, which contains special dye components, sensitizers, and light-sensitive silver halide. On illumination, the silver halide is reduced to one of the primary colors in the layer that has been sensitized. On development, a silver image is first produced in each layer, as in black-and-white photography. An oxidation product of the developing substance is formed at the same time as elemental silver, and this couples with the dye component in each layer to form a dye, thus giving the three colored images. The three silver images are then dissolved oxidatively (bleaching), and the silver halide that has been illuminated is removed with sodium thiosulfate solution. Thus, the remaining colored image does not contain silver. Silver consumption for color photography is lower than that for black-and-white photography per unit of surface area. In all cases, high-purity silver nitrate is the starting material. Recovery of silver in color photography is a complex operation but is nevertheless economical because of the large size of most color processing laboratories.

10.11. Other Uses

Silver halides are incorporated in photochromic glasses [155, 156]. The UV component in daylight liberates elemental silver, so that the glass darkens in sunlight. As the light intensity decreases, colorless silver halide is re-formed, and the coloration decreases. The effect is used mainly in sunglasses. The change in light absorption can vary (e.g., from 10 to 50 % or from 15 to 75 %). Silver chloride in the form of colorless glass-clear films is used in special radiation detectors.

Molecular sieves charged with Ag^+ ions are used in sea rescue for producing drinking water from seawater by the reaction

$$\text{Ag-zeolite} + \text{NaCl} \longrightarrow \text{AgCl} + \text{Na-zeolite}$$

In standard sea rescue equipment, 80 g of zeolite charged with ca. 25 g of silver provides 0.4 L of drinking water.

In an increasingly used alternative to the conventional methods of removing bacteria from drinking water [157], filters containing ion exchangers or activated carbon charged with silver are used. The extent of application of this method (mainly outdoor, camping, caravaning) will depend mainly on limits to the allowable silver content of drinking water in the future. The proposed maximum of 0.01 mg/L Ag is exceeded in this process.

Colloidal silver, mostly in the form of a 1 % solution, is used for disinfection of swimming pools. Effective silver concentrations are ca. 0.1 mg/L. The advantage of the method over hypochlorite treatment consists mainly in the lack of odor. With more highly contaminated water (e.g., in open swimming pools) the effectiveness is generally inadequate.

Silver iodide, generally mixed with sodium chloride, can cause the precipitation of rain or hail if it is dispersed in the form of very small crystals with a particle size of ca. 0.1 μm. These

provide the necessary condensation nuclei. To produce early precipitation of hail, condensation nuclei are distributed in clouds in such numbers ($>100\,000/m^3$) that the hailstones formed are small and not dangerous [158]. Of more importance is the precipitation of rain in barren regions of the Earth.

11. Specifications and Analysis

11.1. Qualities and Commercial Grades

The silver bullion market is usually supplied with "good delivery" silver which is $\geq 99.9\,\%$ pure. While jewelry manufacturers may require alloys in the 80 to 92.5 % range, industrial users require purities of 99.97 %, in, for example, alloying or even 99.99 % for electrical contacts or electroplating.

For trading, the concentrations of individual impurities are in general not taken into consideration, provided their sum does not exceed the required upper limit. If agreed upon, the ASTM Standard Specification for Refined Silver (B 413-97) can be used as a guideline for the chemical composition. There exist also specifications of precious metal refiners (e.g., Degussa), characterizing the quality of their products. Special applications of silver may require particular specifications for individual metallic or nonmetallic trace elements. Table 19 illustrates the range and concentrations of other metals in the "pure" or "fine" silver grades and in the important photographic grade of silver nitrate produced for different users [193].

Silver is supplied mainly in ingot form. For good delivery quality, the ingot mass is generally ca. 31 kg (ca. 1000 oz). Small users usually prefer 1000 g fine silver ingots, although many other masses are available (e.g., cast ingots weighing 5000, 500, and 250 g; stamped bares weighing 100, 50, and 20 g; patterned plates normally 1 oz in mass, or medallions). Crafts men and some industrial users sometimes prefer silver grains, which are sold in sacks up to 20 kg content. Ingots are marked with their net mass in kilograms or troy ounces (1 troy ounce = 31.1035 g).

11.2. Sampling [162–164]

Correct sampling methods are essential for the accurate determination of silver.

Samples are taken from ingots by drilling holes diagonally, or by producing sawings by sawing across the entire cross section at various parts of the ingot. Similar methods are used for semifinished products. If possible, nonhomogeneous materials are melted and cast into ingots that can be sampled.

Waste liquids containing silver may contain sediments and deposits on the vessel walls that can be removed by filtration or dissolution, or samples can be taken after stirring.

Products in lump or powder form that cannot be melted, such as dross, are ground and sieved. The fine and coarse fractions are analyzed separately. If a metallic coarse fraction is obtained, this can be melted.

Special methods have been developed for sampling large amounts of ore, after which the above procedures are carried out.

11.3. Qualitative Analysis [160, 162, 192]

Spectrometric methods, like DC arc optical emission spectrography, flame atomic adsorption spectroscopy (FAAS) [166], inductively coupled plasma optical emission spectroscopy (ICP-OES), inductively coupled plasma mass spectrometry (ICP-MS), and X-ray fluorescence (XRF) are preferred for the qualitative detection of traces of precious metals, the qualitative investigation of small quantities of material, and the identification of precious metals in mixtures and alloys.

Amongst *chemical detection procedures,* the precipitation of silver as chloride from nitric acid solution is the most common, with as little as 0.1 μg/L detectable by the appearance of turbidity. In contrast to other sparingly soluble chlorides, silver chloride is soluble in ammonia solution.

The formation of colored complexes of silver, e.g., the redviolet complex with *p*-dimethylaminobenzylidenerhodanine or the yellow dithizonate [165], is seldom used for qualitative analysis because of possible interference by other metal ions.

Table 19. Specifications of pure silver products

Name	Silver content, %	Content of other metals µg/g	
Good-delivery silver	≥ 99.9	Cu	≤ 900
		others	≤ 100
Fine silver	≥ 99.97	Cu	≤ 250
		others	≤ 50
		including	
		Pb, Bi, Fe	≤ 10
		Se, Te	≤ 5
		total	≤ 300
Fine silver	≥ 99.99	Cu	≤ 50
		others	≤ 50
		including	
		Au, Bi, Cd, Fe, Ni, Pb, Pb, Pd, Pt, Rh, Sb, Se, Te, Zn	≤ 5
Fine silver, chemically pure	≥ 99.995	Cu	≤ 15
		others	≤ 35
		including	
		Pb, Fe	≤ 5
		Au, Bi	≤ 1
Fine silver, high purity	≥ 99.999	Al, Fe, Si, Sn	≤ 2
		Pb, Au	≤ 1
		Cd, Bi	≤ 0.5
		Cd, Mn	≤ 0.4
		total	≤ 10
Silver nitrate, photographic grade	63.5	Range of requirements of users Na, K, Ca, Mg	1 – 5
		Al, B, Cd, Cr, Cu, Fe, Pb, Mn, Ni, Sb, Se, Te, Tl, Ti, Sn, Zn	0.05 – 1
		Bi, Hg, Au, Pt, Pd, Ir, Rh, Ru	0.001 – 0.01
		nitrite	1 – 2
		sulfate	10 – 20
		chloride	1 – 5

Silver halides can be digested by fusion with $NaKCO_3$. The silver is precipitated in metallic form and can be separated by dissolving the melt in water.

Fire assay with lead as collector [160, 161] can also be used for qualitative analysis. Here, all the base metals in a powder sample are converted to slag, leaving a bead of silver and lead.

11.4. Quantitative Analysis [23, 159–162, 192]

A large proportion of the 15 000 t/a silver used by industry with a total value of ca. 4×10^9 DM is converted into silver nitrate, alloys, or into many varied forms. Calculations of the costs of production require accurate analysis of the silver contents of the products and residues. The purchase of residues and operation of recovery processes has similar needs.

Fire assay procedures (see also → Gold, Gold Alloys, and Gold Compounds, Chap. 9.3.), which have been used for hundreds of years to analyse silver and gold, are still important for the quantitative analysis of silver. *Scorification* is the fusion of the sample material with granulated lead by adding some borax or soda under oxidizing conditions in a cupellation furnace. Part of the lead remains in metallic form as precious metal collector, and another part is oxidized to PbO, which, in liquid form, dissolves the base metal oxides and forms a slag. The scorification method can be applied to the analysis of a variety of materials containing silver, such as ores, smelting products, and residues, whose silver contents are not less than ca. 0.1 %.

The aim of the *classical crucible method* is to collect the silver or, more generally, the precious metals of the sample material in a lead regulus, and at the same time scorify the base matrix components. To this end, the sample is mixed with lead oxide, a reducing agent such as charcoal or flour, and a flux as slag producer. The crucible method with lead is a procedure with a great variety of applications for enrichment and separation of precious metals. It can be applied to many metallic and nonmetallic products con-

taining silver from the ng/g up to the high percentage range.

After collecting the silver in lead, the collector metal is removed by an oxidation process (*cupellation*). Proofs are run in parallel so as to make corrections for cupel absorption and some evaporation of silver. In principle cupellation is appropriate also for silver determination in alloys. But the greater accuracy achievable with potentiometric titration means that the cupellation method is now seldom used for silver alloys.

Physical Methods. In systems of known constitution (e.g., silver brazing alloys or jewelry alloys), *X-ray fluorescence analysis* can be carried out [172–174] with an accuracy adequate for stock control.

Optical emission spectroscopy with glow discharge (GD-OES) can also be used for the quantitative determination of silver in its alloys [194].

ICP-OES of solutions with the emission lines at 328.07 and 328.29 nm is being used increasingly for precision analysis of silver. The prerequisite is the application of the principle of internal standardization, e.g., with yttrium (see → Gold, Gold Alloys, and Gold Compounds, Chap. 9.3.).

Gravimetric and Electrogravimetric Determination. Given the availability of precise physical methods, the gravimetric determination of silver by precipitation of silver chloride is no longer applied. However, the electrogravimetry of silver from cyanide solutions remains important. This method can be used for silver determinations in photographic industry scrap, which contains sparingly soluble compounds such as silver halides.

Volumetric Determination. In nitric acid or sulfuric acid solutions, silver is determined by titration with a standardized alkali halide solution with potentiometric indication of the equivalence point by using a halogenated silver electrode in combination with a $Hg/HgSO_4$ reference electrode [160–162, 167, 168, 197]. Automatic titrators which work with dynamic volume dosing are available. It is the preferred method for silver alloys, e.g., coin and jewelry alloys [195], unrefined and auriferous silver, electrotechnical alloys, recovered scrap alloys and silver catalysts, anode sludge from copper electrolysis, and others. In principle it is usable from ca. 0.1 to nearly 100 % silver. The potentiometric titration of silver has nearly completely replaced the titration method according to Gay-Lussac, in which silver in nitric acid solution is titrated with a NaCl solution with visual observation of the so-called clear point or endpoint. The potentiometric determination of silver is less subject to interferences than Gay-Lussac titration. It has become one of the most important methods of silver determination.

An alternative titrimetric method is the precipitation of Ag_2S with a solution of thioacetamide (CH_3CSNH_2). The endpoint is detected by voltammetry [169, 198]. The determination of the EMF of a silver-sensitive electrode [168, 170] should also be mentioned.

11.5. Purity Analysis

For most pure silver, the fineness is determined by subtracting the sum of the impurities from 100 %. The most important methods for the determination of trace impurities in silver are spark discharge OES (SD-OES) [196] and GD-OES [175, 194] on fused or pressed metallic samples. These methods allow rapid simultaneous determinations of the trace elements. The area of their application begins with good delivery silver (99.9 % Ag) and ranges via fine silver with 99.99 % Ag to chemically pure fine silver with 99.995 % Ag. With silver of a higher degree of purity it is better to use other methods, such as GD-MS.

Stringent purity requirements are imposed on the most important silver compound, silver nitrate, for which metallic (cationic) impurities can be checked by means of IC-OES and graphite furnace atomic absorption spectroscopy (GFAAS). Especially advantageous is the use of an ICP spectrometer with axial plasma, an echelle grating optical system, and a solid-state detector (type CID or SCD) [193]. ICP-MS is a very suitable technique for silver nitrate analysis on account of the low detection limits [193].

11.6. Trace Analysis

Detection limits of ca. 0.5 μg/g of silver in ores and rocks can be achieved by using optical spec-

trography with arc excitation with the 328.1 nm and 338.3 nm lines. If the material can be dissolved, typical detection limits are 0.001 µg/mL with FAAS [166], 0.002 µg/mL with ICP-OES, and 0.02 ng/mL with ICP-MS. XRF can also be used for trace detection, albeit with matrix-dependent detection limits.

The allowable concentration of silver in wastewater is low because of the widespread use of biological wastewater treatment. Silver(I) ions interfere with the biological equilibrium at a concentration ≥ 0.04 mg/L. FAAS or ICP-OES are widely used for wastewater analysis.

Trace analysis of precious materials in waste materials such as slags and wastewater from the precious metal industry, especially scrap recovery plants, is of great importance for checking the economic efficiency of the process.

11.7. Argentometry [167,168]

The precipitation reactions used for volumetric determination of silver can also be used for determination of ions that form insoluble precipitates with Ag^+. Titration techniques for determining chloride, bromide, iodide, cyanide, thiocyanate, etc. are generally known as argentometry.

12. Economic Aspects [15,16,23]

12.1. Production

Of all the noble metals, silver comes first in terms of annual production. Sources of supply are mine production, material from recycled scrap, and additional material from net official sales, from hedging and from implied disinvestment.

World silver supply in 1998 is summarized in the following:

Mine production	16 969 t
Recycled silver scrap	5934 t
Net official sector sales	1613 t
Hedging	158 t
Implied disinvestment	1470 t
Total	26 144 t

Figure 51 gives a survey of the proportion of quantities of silver produced by mining, ranked by country in relation to the total silver supply.

Figure 51. World silver supply in 1998 (mine production by country, scrap, trade)

Mine production is the biggest source with about 65 % of the total supply. Silver is produced from primary silver ores and as byproduct from gold, copper and lead – zinc mines (Fig. 52). The biggest mines (with output in 10^6 oz) are located in Mexico (Industrias Penoles 36.4, Grupo Mexico 16.1), Poland (KGHM Polska Mieds 35.3), Australia (BHP Minerals 18.1), U.K. (Rio Tinto 16.2), Canada (Cominco Ltd. 13.3, Noranda 11.2), Peru (Cia. de Minas Buenaventura 10.8). Their production amounted in 1998 to one-third of the total mine supply.

Figure 52. Silver mine production by source in 1998

The amount produced is relatively insensitive to price movements, which are sometimes large and generally of a speculative nature, because silver is mainly a side product of the extraction of base metals. Also, market price fluc-

tuations are reflected to only a limited extent in production from recycled materials. However, government sales, and sometimes purchases, are strongly dependent on price changes. Sales of silver from the CIS have a relatively small influence on the total supply situation in the Western world in spite of the considerable production in this region. Also, in comparison to gold and the platinum-group metals, large amounts of silver are frequently released to the world market from the old stocks in India, estimated at around 120 000 t. This material was accumulated many years ago from domestic production and commercial transactions. The total stocks of the Western world (excluding India) amount to ca. 80 000 t, of which approximately 50 % is owned by the U.S. government.

12.2. Demand

Figure 53 give a survey of the percentage in the most important application fields. The biggest part is the photographic sector (main product silver nitrate), with radiography (38 %), consumer papers (22 %), consumer films (15.1 %), and graphic arts (13.5 %), followed by jewelry and silverware, and electrical technology and electronics. The term "general industrial applications" in the following list refers to various fields such as the use of silver and silver compounds in catalyst, batteries, mirrors, bearings, and bactericides.

Figure 53. World demand for silver by application (percentage of total demand)

World silver demand in 1998 was as follows:

Photography	7628 t
Jewelry and silverware	7601 t
Electrical/electronic	4307 t
Brazing alloys and solders	1200 t
General industrial applications	4559 t
Official coins	849 t
Total	26 144 t

The demand for silver (Fig. 52) is fairly well matched by the supply. However, the relatively small extent of known silver reserves in ores, compared to other metals, could in the future lead to a change in stockpiling practice. In technology, an important factor in the future is likely to be a decrease in the importance of classical silver-based photography, to the benefit of electronic image-making techniques.

12.3. Silver Market and Trading

The most important silver exchanges are the New York Commodity Exchange and the TOCOM in Tokyo. The London Bullion Market Association (LBMA) provides through some of its members one spot price information per day: the London Silver Fixing.

The amounts of silver transferred yearly are often many times greater than the world's demand for silver.

On June 22, 1992, the price of silver was $ 4.30 per ounce, having remained around this low level for many years. The low point of $ 3.65 per ounce reached in 1972 was again reached in 1992.

In February 1998, the investment fund of Warren Buffet announced having bought more than 4000 t of silver in the proceeding months based on a perceived long term supply/demand deficit. The price of silver thereafter on speculative buying shot to $ 7.81 per ounce on February 6th. Failing any follow through, the silver price retreated to below $ 5.00 per ounce by August 1998.

13. Toxicology, Occupational Health, and Safety

13.1. Toxicology

Silver and its compounds are much less toxic than other heavy metals and their compounds

because silver compounds are very poorly absorbed in the gastrointestinal tract; in addition, they are rapidly converted into insoluble compounds or complexed by metallothioneine. Acute silver poisoning occurs when colloidal silver is administered parenterally in high doses [200]. Silver nitrate or silver fluoride can cause tissue damage because of their caustic properties. Gastroenteritis, diarrhea, drop of blood pressure, cramps, paralysis, and respiratory arrest were observed as poisoning symptoms. A 10 % aqueous silver nitrate solution seriously damages the eye [201].

Adverse effects (anemia, growth retardation, liver necrosis, and fatty degeneration of liver and kidneys) have been observed when animals were treated with repeated doses of silver salts [203, 204]. Implantation of silver foil or injection of colloidal silver caused local tumors in rats, probably as an unspecific reaction to foreign bodies but not a true carcinogenic effect [205].

In Germany, the MAK value for silver metal has been fixed at 0.1 mg/m^3 and for silver compounds at 0.01 mg/m^3. This low value suggests a high toxicity, but it has been set at one tenth to one hundredth of that for other heavy metals to certain prevent argyria (see below). The TLV for silver metal has been set at 0.1 mg/m^3 in the United States and other industrialized countries. BAT values for blood and urine that corresponds to the MAK values could not be determined as yet. Usual base values in these fluids are lower than 1 µg/L, even in workers with high exposures to silver dust [206, 207].

According to German law (Trinkwasserverordnung) drinking water must not contain more than 10 µg/L of silver.

Argyria. Argyria is the consequence of chronic intake of silver salts, colloidal silver, or finely divided silver metal that leads to local accumulation of silver and causes gray to brownish discoloration of the skin, especially of areas exposed to light [202]. Localized argyria is the result of direct silver intake of the skin. Generalized argyria follows absorption of silver from the gastrointestinal tract or by parenteral administration [208]. The symptoms are irreversible and cannot be treated by medication. Apart from the dark skin and local silver accumulation in internal organs, no systemic poisoning is observed. Particulary workers in the silver nitrate and silver-plating industries are at risk argyria. As a result of better workplace hygiene, the condition has become rare.

13.2. Ecotoxicology

Bacteria, some fish and other waterborne species are more sensitive to silver salts than other animals and plants.

Usually silver and its compounds do not constitute an environmental problem. However, the discharge of silver and its compounds into surface water needs special attention due to their toxicity to some species [203]. The U.S. EPA has classified the precious metals silver, gold, platinum, and palladium (and other "classical" heavy metals) as "very poisonous" and "easily available". The other platinum group metals have been assigned to the middle class (poisonous, but not easily dissoluble or rare).

Bactericidal Effect. The metabolism of bacteria is adversely affected by silver ions at concentrations of 0.01 – 0.1 mg/L. Therefore, even less soluble silver compounds, such as silver chloride, also act as bactericides or germicides, but not the much less soluble silver sulfide.

In the presence of atmospheric oxygen, metallic silver also has a bactericidal effect due to the formation of silver oxide, which is soluble enough to cause it. Bactericidal concentrations are produced extremely rapidly by adding colloidal silver, which has a high surface area, but even objects with a solid silver surface (e.g., table silver, silver coins, or silver foil) have a bactericidal effect in the absence of sulfide, which would otherwise combine with the Ag^+ ions.

The death of microorganisms such as bacteria, molds, spores, and fungi on contact with silver articles was discovered by von Nägeli (1817 – 1891), although he did not identify the cause. The effect was certainly used in antiquity, and silver drinking vessels were carried by military commanders on expeditions for protection against disease. Nägeli named the effect that he discovered the oligodynamic effect. This is now generally understood to mean the damaging effect of very small amounts of metallic cations on living cells.

13.3. Explosion Hazards [19]

Silver forms many unstable compounds (see Section 7.7) that can explode or detonate on thermal or mechanical stress, on drying, under the influence of light, or sometimes spontaneously without any known cause. This group includes several nitrogen compounds (e.g., AgN_3, $AgNH_2$, AgCNO) of silver, organic compounds (especially silver acetylide and its derivatives, also $(COOAg)_2$), and silver(II) oxide in contact with finely divided organic materials.

Since some of these compounds can be formed by reaction with elemental silver, acetylene and ammonia in the gaseous or liquid state should not be allowed to come in contact with items of equipment made of silver or its alloys. Also, silver and its compounds must be kept away from acetylene flames.

Silver salts of strongly oxidizing acids (e.g., silver chlorate and nitrate) can lead to dangerous explosions on contact with oxidizable materials (e.g., organic substances, sulfur, soot). Contact of silver nitrate with alcohol leads to immediate formation of explosive silver fulminate. Many explosions have resulted from formation of nitride in ammoniacal solutions of silver. Silver oxalate is reported to decompose at 140 °C, but explosions have occurred on drying at 80 °C.

1. Introduction

The present world population stands at more than 5×10^9 people, about 10 % of whom go hungry. More than 10^9 people in developing countries lack sufficient food to maintain their health and productivity. A clear challenge thus exists not only to overcome current food shortages, but also to provide sufficient food for the population of tomorrow. Actually, food as such is not the problem, because carbohydrates and fats are plentiful. The real problem is proteins (→ Proteins), which supply essential amino acids that cannot be replaced by other substances (→ Amino Acids). A diet deficient in these amino acids results in severe physical damage and disease.

At present, ca. 20 % of the dietary protein for the world's population comes from animal sources, ca. 55 % from grain cultures, ca. 17 % from oilseeds, and ca. 8 % from fruits and vegetables. In general, animal protein has more nutritional – physiological value than plant protein. With less animal protein in the diet, a greater quantity of total protein must be consumed. Therefore, because of an inadequate supply of animal protein (only ca. 9 – 30 % of the total), people in developing countries are forced to consume considerably more plant protein than is readily available.

In the search for new and alternative protein sources, and above all to facilitate the production of protein-rich food under difficult climatic conditions, single- cell organisms showed promise of becoming an attractive solution. In comparison with animals and plants, microorganisms are characterized by higher rates of protein synthesis and greater protein content. They are also less demanding than animals with regard to nutrients. For instance, whereas microorganisms can accept inorganic sources of nitrogen, animals require organically bound nitrogen. The same principle applies to sources of carbon. Furthermore, industrial-scale production of microorganisms can be carried out in reactors using continuous processes that are independent of climatic and weather conditions and require little space (→ Biotechnology). Like animal and plant protein, protein from microorganisms offers both advantages and disadvantages from a qualitative standpoint.

In 1966, C. Wilson at the Massachusetts Institute of Technology coined the term "single cell protein" (SCP) [1] as a way of describing dried cells from bacteria, yeasts, fungi, algae, and higher fungi produced on a large scale as a source of protein for food and feed. The terms *microbial biomass*, *microbial cell substance*, and *bioprotein* are used synonymously.

Unicellular organisms have played an important part in human nutrition for thousands of years: yeasts, especially *Saccharomyces cerevisiae*, in the preparation of wine and beer as well as in baking (→ Yeasts), and bacteria, for instance of the genus *Lactobacillus*, in cheesemaking (→ Cheese, Processed Cheese, and Whey) and in the preservation and processing of natural products [2]. Both of these applications take ad-

vantage of the biocatalytic potential of microorganisms. The utilization of microorganisms as primary producers of proteins and vitamins is a concept of the twentieth century [3], the root of which can be found in the "Vienna process" for the production of baker's yeast (A. J. MAUTNER, ca. 1850).

The first methods for producing SCP were developed in Germany, and are closely associated with the names of J. SCHECKENBACH, M. DELBRÜCK, and W. HENNEBERG. Originally, molasses (World War I) and later sulfite waste liquors served as the raw material [4]. The first yeast factory based on sulfite waste liquor was opened in Björneberg, Finland, in 1928. Conditions suitable for the continuous production of yeast from sulfite waste liquor were established by H. FINK, J. KREBS, and R. LECHNER in the years following 1937. Large-scale production facilities were developed by H. SCHOLLER (mammoth pump system) and M. E. PEUKERT (Phrix system) in the case of wood hydrolyzates, and by W. CLAUS (Waldhof system) for beechwood sulfite waste liquor [5]. Fermenters used today are still based on these three fundamental types. Fodder yeast has been produced industrially in Germany since 1940 on the basis of waste products, including molasses and distillery residues. In 1944, six large-scale plants were producing a total of about 15 000 t/a of dry yeast. (These plants were designed for an annual production of 80 000 t [6].) At this time it was discovered (F. JUST and W. SCHNABEL) that yeast is also capable of growing on hydrocarbons. This finding set the stage for development in the early 1960s of industrial processes based on hydrocarbons (J. C. SENEZ and A. CHAMPAGNAT). The first large pilot plant designed around diesel fuel was operated by British Petroleum in Lavera, France [7–9]. Two 100 000 t plants were erected in Italy, but these were never put into operation [9]. From 1983 to 1990, fodder yeast was produced from petroleum distillate in Schwedt near Frankfurt/Oder, former German Democratic Republic [10]. In the former Soviet Union, production of SCP, yeast, and bacteria from both hydrocarbons and carbohydrates amounted to more than 1×10^6 t/a. In the 1970s, another raw material was introduced for the production of SCP, methanol. Imperial Chemical Industries led in this development and operated a large-scale production facility for several years [7, 11].

A number of processes for the industrial-scale production of SCP have been developed (Table 1), but only a few are currently operating, essentially for economic reasons (see Chap. 6).

2. Substrates and Organisms

In accordance with the elemental composition of cellular material ($C_aH_bO_cN_d \ldots$), its biosynthesis (i.e., growth and multiplication) requires the elements carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur, as well as calcium, magnesium, sodium, etc., (see Chap. 4). Organisms are able to incorporate the structure-forming elements either in their free or molecular form (O_2, H_2, N_2) or in combination with other elements (as NO_3^-, $C_xH_yO_z$, NH_4^+). Carbon is not utilized in its elemental form, but is assimilated as carbon dioxide or in some more or less reduced state ($C_xH_yO_z$).

With CO_2 as the sole source of carbon for growth and multiplication (autotrophic nutrition), an additional energy donor is required (e.g., H_2, Fe^{2+}, or thiosulfate for chemolithotrophic organisms, light in the case of phototrophic organisms). Carbon dioxide is the source of carbon for algae, cyanobacteria, and *Knallgas* bacteria (e.g., *Alcaligenes eutrophus*). The latter were considered as possible sources of SCP in the 1960s [14]. On the other hand, carbon compounds of the type $C_xH_yO_z$ ordinarily serve simultaneously as sources of energy (chemoorganoheterotrophic nutrition), and they are the basis of industrial processes involving bacteria, yeasts, and molds. The synthesis of SCP by growth and multiplication of microorganisms proceeds under aerobic conditions, because yield coefficients are higher than under anaerobic conditions.

Substrates of the type $C_xH_yO_z$ can be of agricultural, forest (carbohydrate), or petrochemical (hydrocarbon) origin. Accordingly, two groups of raw materials can be distinguished: renewable and fossil. The use of renewable (conventional) sources of carbon as substrates for biotechnological processes has the longest tradition. These originate photoautotrophically as starch or cellulose, and are usually made available for biotechnological conversion in the form of waste prod-

ucts from the chemical and food industries or from farming (sulfite waste liquor, molasses, distillery residues, or whey). The easily assimilated substances in these materials are sugars, low molecular mass alcohols, and acids. In the group of fossil (nonconventional) raw materials and petrochemicals, the easily assimilated carbon compounds that have attracted the most attention are the longer-chain *n*-alkanes, but also methane and methanol, where the latter can be prepared in very pure form from natural gas, synthesis gas, or cellulose (via synthesis gas).

The most important microorganisms so far exploited for industrial production are listed in

Table 2; many others have also been identified and tested for their suitability. However, processes are often not based on a single defined microbial species, and the nutrients utilized are often chance mixtures of substances (waste) that do not have a constant composition. In principle, both bacteria and yeasts (molds) are potential candidates for the chemoorganoheterotrophic synthesis of SCP. As a rule, bacteria grow more rapidly and efficiently than yeasts, and they provide a higher content of crude protein, sulfur-containing amino acids, and lysine – but also of nucleic acids, which is unfavorable from a nutritional – physiological viewpoint (see Chap. 5). Bacteria are only about one-tenth the size of yeast cells, and they often have an unpleasant odor. Yeast culture is better established.

The development of any bioindustrial process involving cells or organisms starts with selection. If the organisms are to be used as a catalyst for the synthesis of metabolites (e.g., ethanol, citric acid, amino acids, penicillin, etc.), known as "overflow production", the objective of selection is defined qualitatively by the target product itself. In the case of SCP it is protein that is, strictly speaking, the aim and purpose of the process. Any microorganism is a potential candidate if it is capable of growing on the projected raw material. Factors such as pH and temperature, or prototrophy (demand for supplementary materials, e.g., vitamins, called *suppline*), can all be taken into account in the selection program. One cannot select for attainable protein content and protein quality, or for growth efficiency, but selection for growth rate is possible. Because there is a correlation between growth rate and growth efficiency [15], the most rapidly growing microorganisms are the ones subjected to further screening. These are usually also the ones that hold their own in the competition for substrate in an unprotected process.

3. Efficiency Considerations in the Selection of Substrates and Microorganisms

Efficiency of growth and multiplication are reflected in growth-yield coefficients expressed, e.g., in grams of dry weight formed per gram of substrate consumed. A knowledge of efficiency limits is a valuable starting point in the choice of substrates, the selection of organisms, and the optimization of processes. The maximum possible yield of biomass depends on the substrate and, for a given substrate, on the organisms selected (i.e., it is genotypically determined; see Table 3).

A yield can be calculated in advance [16, 17] on the basis of a division of the growth and multiplication processes along metabolic lines as follows:

Synthesis of a central precursor, which serves as the starting point for synthesis of all cell constituents

$$C_xH_yO_z \longrightarrow \text{Central precursor} + E_a\ (+2H + CO_2^{a1})$$

Synthesis of cellular material, anabolism

$$\text{Central precursor} + NH_3 + E\ (+2H) \longrightarrow C_aH_bO_cN_d + CO_2^{a2}$$

Energy (E) for the synthesis of cellular material can be made available during the synthesis of the precursor (assimilation, E_a). If this amount of energy is insufficient for maximum conversion of precursor carbon to cellular material, then more substrate must be consumed (dissimilated) solely for the purpose of supplying energy (E_d):

Generation of "biological" energy by complete oxidation of the substrate

$$C_xH_yO_z + O_2 \longrightarrow CO_2^d + E_d + H_2O$$

(CO_2^a = assimilatory CO_2 loss; CO_2^d = dissimilatory CO_2 loss; $E_{a,d}$ represent ATP and/or energetically valuable reduction equivalents, and 2H stands for bioenergetically valueless reduction equivalents; $E = E_a + E_d$)

The fictitious cell molecule $C_aH_bO_cN_d$ can be regarded as $C_4H_8O_2N$ in the case of bacterial biomass and $C_6H_{10}O_3N$ for yeast biomass. Differences in these specifications that arise from biomasses of differing composition can be neglected [16], because their effects on cell yield calculations are small, although the energy expenditure required for synthesis of the primary components (proteins, carbohydrates, lipids, and nucleic acids) varies greatly. (The synthesis of 1 g of protein or 1 g of nucleic acid consumes about three times as much energy as the synthesis of 1 g of carbohydrate [16, 18].) For protein and carbohydrate content ranges of

			Spirulina sp.

40 – 55 % and 20 – 35 %, respectively, the calculated yields of yeast dry mass are 0.35 – 0.38 g per gram of methanol, and 0.46 – 0.49 g per gram of glucose [19].

If the expenditure of energy for the synthesis of cell substance from a central precursor is regarded as approximately constant and independent of substrate, then the amount of energy supplied in the course of assimilation (E_a) is decisive in establishing whether the potential growth efficiency based on carbon metabolism can actually be achieved, or whether the growth yield is energy limited.

E_a is determined by the substrate and, for a given substrate, by the metabolic pathway, as shown by the balanced equations for synthesis of a central precursor (3-phosphoglyceric acid, PGA, in this case):

$$0.5\ \text{Glucose} \xrightarrow{\text{EMP}} 1\ \text{PGA} + 1\ \text{NAD(P)H}$$

$$0.5\ \text{Glucose} \xrightarrow{\text{ED}} 1\ \text{PGA} + 1\ \text{NAD(P)H} - 1\ \text{ATP}$$

$$3\ \text{Formaldehyde} \xrightarrow{\text{serine}} 1\ \text{PGA} - 3\ \text{ATP} + 1\ \text{FADH}_2$$

$$3\ \text{Formaldehyde} \xrightarrow{\text{HuP}} 1\ \text{PGA} + 1\ \text{NAD(P)H} - 2\ \text{ATP}$$

(EMP = Embden – Meyerhof – Parnas pathway; ED = Entner – Doudoroff pathway; serine = serine pathway, isocitrate-lyase positive variant; HuP = hexulose phosphate pathway, fructose-1,6-bisphosphate variant.)

The experimentally obtained yield coefficients (Y values) of ca. 0.35 g or 0.5 g of bacterial dry weight per gram of methanol (serine and hexulose phosphate pathways, respectively) are undoubtedly attributable to this factor (see Table 3) and not to differences in the efficiency

Table 3. Theoretical and experimental growth yield coefficients [grams of biomass dry weight per grams of substrate (Y) or per grams of oxygen ($Y_{X/O}$)] [16]

Substrate	Bacteria					Yeasts

Y = grams of dry substance per gram of substrate at carbon conversion of 85 or 75 %; Y_{exp} = observed yields; Y_{calc} = yields calculated according to the Y_{ATP} concept [16–18]; numbers in parentheses: extent of carbon conversion based on the hypothetical cell molecule $C_4H_8O_2N$ for bacteria and $C_6H_{10}O_3N$ for yeast. [a] Serine pathway. [b] Hexulose phosphate pathway. [c] Mixed culture.

of energy recovery via electron-transport phosphorylation.

In the case of glycolytic substrates (C_{3n}), the carbon conversion efficiency is ca. 85 %, and for nonglycolytic substrates (gluconeogenetic, C_{2n}), ca. 75 % [19]. Therefore, all substrates for chemoorganoheterotrophic growth are more or less energy deficient (see Table 3). Ethanol is an exception, and probably provides a surplus of energy [20]. Based on the ratio $Y_{exp}/Y_{100\,\%}$, ethanol would be the substrate of choice for the production of SCP if all possible substrates were freely available. This is not necessarily the case, however, when the cost of raw materials, possible productivities, and growth-yield coefficients based on oxygen (Table 3) are included in the economic considerations.

In principle, yields in excess of the Y_{calc} values listed in Table 3 are possible. One approach to this end is to combine substrates in such a way that, in the course of their simultaneous utilization, a minimum amount of carbon is dissimilated for the purpose of supplying energy. This is apparently the case with the mixture sucrose – acetic acid – ethanol (Table 4), in which ethanol cannot possibly compensate for the energy deficits of sucrose and acetic acid. Instead, as in the case of a methanol – glucose mixture, the observed auxiliary substrate effect must be a result of metabolic channeling ("division of function") [22].

Another approach is provided by genetic engineering. In the case of *Methylophilus methylotrophus*, replacing the energetically more elaborate glutamine synthetase – glutamate synthase cycle for the fixation of ammonia nitrogen by glutamate dehydrogenase led to a ca. 5 % increase in the growth yield [23].

An even more pronounced effect (up to 30 %) is to be expected from manipulation of the carbon metabolism (e.g., if the pyrroloquinoline quinone (PQQ) dependent methanol dehydrogenase in bacteria [24] or the energetically worthless methanol oxidase in yeasts were to be replaced by a nicotinamide adenine dinucleotide (NAD) dependent methanol dehydrogenase [16]).

The actual objective is, of course, the production of protein, but more syntheses take place in the course of chemo- and phototrophic nutrition. Other essential structural and functional components of cellular and organismic systems are the carbohydrates, lipids, and nucleic acids mentioned above. Irrespective of whether microorganisms synthesize their cell substance from carbon dioxide or hydrocarbons, for example, es-

Table 4. Growth yield coefficients with *Candida* and *Saccharomyces* species on single substrates and a substrate mixture [21]

Mixture *			
Expected		1.14	57
Obtained		1.35 **	67.5

* Mixture ratio: 0.7 g sucrose – 1.0 g acetic acid – 0.6 g ethanol.
** Auxiliary substrate effect: 118 % compared to the additive (expected) value.

sentially the same macromolecules or polymers are always formed despite chemically very diverse precursor carbon skeletons. In all cases, optimally growing and multiplying microorganisms (unlike resting cells) are composed of relatively constant proportions of the primary components listed. This fundamental observation is not affected by the fact that bacteria differ from yeasts in, e.g., their (crude) protein content.

Thus, protein content would appear to be independent of substrate. However, there are indications that protein content increases with substrates that are richer in energy [25], and can also be increased by improving the energy – carbon ratio [26]. For a given organism – substrate combination, the protein content is highest (with continuous growth according to the chemostat principle) when the growth rate is limited by the carbon source.

Protein quality (amino acid composition) is a function of genotype. It may also be phenotypically influenced by the substrate and, in the broadest sense, by nutritional or culture conditions. This is because, depending on the substrate, enzymes with variable amino acid spectra may serve to catalyze the same event. Nevertheless, it is highly improbable that such changes in enzyme content would lead to a significant increase in a particular amino acid.

In the following considerations, the essential amino acid lysine will serve as an example to substantiate this assumption. In principle, the lysine content of the total protein in bacteria or yeasts could be increased either by increasing the lysine content of individual proteins (enzymes), or by introducing an additional protein consisting exclusively of lysine, whereby this polylysine would need to represent a relatively high fraction of the total protein present. Lysine is coded by the triplets AAA and AAG. Synonyms for lysine arise through mutation (transition, transversion) in the codons for arginine, asparagine, glutamine, threonine, and glutamic acid (one base, two triplets each), and isoleucine and methionine (one base, one triplet each). This means that point mutations could increase the lysine content in defined proteins, especially at the expense of arginine (16), asparagine (13), glutamine (9), threonine (7), and glutamic acid (6). (The numbers in parentheses indicate the frequency of observed replacements.) Glycine and proline, as well as alanine and serine, have also been found to be exchanged for lysine in homologous proteins, although in these cases mutations are required in more than one base.

The lysine content of proteins varies between ca. 2 g and 12 g per 100 g of protein [i.e., ca. 35 to 90 lysine residues for every 1000 amino acids (molecular mass ca. 110 000) in a protein (enzyme)]. If the lysine content of a specific protein is to be increased by 1 g/1000 g, ca. 6 mutations are required based on 1000 positions. Since the lysine content of the total protein is to be increased, exchange of this type would be necessary within each of at least 1000 different proteins, or at least in one or several of the proteins representing a high proportion of the total protein content. Another requirement for success is that any mutation or exchange must not be lethal; in other words, it must result in functioning, isodynamic enzymes. If the lysine content were to be increased at the expense of the above-mentioned amino acids, then there would certainly be an observable effect on growth efficiency. In addition, increased incorporation presupposes a higher rate of synthesis, which means not only that the genetic code must be "prepared" for the increased incorporation, but the metabolic regulation must allow it (feedback regulation).

4. Technology and Equipment

SCP synthesis is achieved through the growth and multiplication of microorganisms. Establishing an optimal set of conditions (phenotypic optimization) requires that the performances (in terms of yield, rate, etc.) of the microorganisms must be investigated first on a laboratory scale as a function of such conditions as pH, temperature, and residence time. Decisions can also be made at this stage about whether a protected (sterile) or open process is preferable, and whether it should be carried out in batch, fed-batch, or continuous mode. In general, continuous processes are preferred for SCP synthesis. Chemostatic cultivation – in which residence time is adjusted via the carbon substrate feeding rate – is optimal with respect to the target function. Gradients in the substrate supply must be avoided, because these constitute disturbances, and would lead to reduced yields.

For microorganisms that grow effectively in the neutral pH range, protection (air filters, sterilization of the nutrient solution, etc.) is essential to prevent contamination by unwanted organisms.

Table 5. Inorganic additives for a typical nutrient solution used to culture microorganisms

Compound	Additive – dry substance ratio, mg/g
NH_4OH	80 – 135
H_3PO_4	15.00
KOH	10.00
$MgSO_4 \cdot 7\,H_2O$	2.00
$CuSO_4 \cdot 5\,H_2O$	0.07
$CoSO_4 \cdot 7\,H_2O$	0.02
$MnSO_4 \cdot 5\,H_2O$	0.06
H_3BO_4	0.05
$FeSO_4 \cdot 7\,H_2O$	0.14
$ZnSO_4 \cdot 7\,H_2O$	0.07
$Na_2MoO_4 \cdot 2\,H_2O$	0.02

Semitechnical and pilot-scale experiments provide the data required for scale-up, together with process parameters important in the design of a large-scale plant.

An industrial production facility usually consists of separate stations for the following functions:

1) Preparation of the substrate and the nutrient medium
2) Substrate conversion (by growth, fermentation)
3) Separation and concentration of the product
4) Evaporation and drying
5) Product formulation

Not all substrates require "preparation". If the raw materials contain starch and cellulose, preparation involves digestion (acid- or enzyme-catalyzed hydrolysis), pH adjustment, and, if necessary, removal of growth-inhibiting substances (e.g., SO_2 or furfural from sulfite waste liquor [5]).

Preparation of the nutrient medium involves mixing and dissolution. All substances that the production organism cannot itself synthesize must be added with the nutrient solution. In most cases, the microorganisms are prototrophic, so only the carbon and energy source is of an organic nature. Essential ions and their required levels are determined from cell analyses (Table 5).

The synthesis of cell substance (fermentation, growth) takes place in fermenters, and involves two basic process engineering operations:

1) Stirring and mixing of a multiphase system (solid – liquid – gaseous; i.e., microorganisms, aqueous fermentation solution, and air)
2) Transport of oxygen in the dissolved state from the gas bubbles, through the fermentation liquid, to the microorganisms

Supplying dissolved oxygen to the microorganism cell (i.e., the rate of oxygen transfer) is usually the growth rate-limiting step that determines the efficiency of an overall fermentation system.

Stirred-tank, tubular loop, and deep jet reactors [27] have all been employed for the production of SCP because they provide high oxygen-transfer and dispersing efficiencies [28]. Deep jet fermenters transport up to 12 kg of O_2 per ton of fermenter content per hour without pressure, and 50 kg of O_2 per ton of fermenter content per hour at pressures up to 0.1 MPa. Reactor volumes up to several thousand cubic meters are feasible. The choice of conditions must of course take into account technological and reaction engineering criteria, but also biological factors such as the fragility of microorganism cells in the shear field of a stirrer, cell response to inhomogeneities in the fermenter (gradients

Figure 1. Facility for the production of Fermosin [former VEB Petrochemisches Kombinat Schwedt/Oder, German Democratic Republic, in operation from 1985 to 1990; output 55 500 t/a; equipped with two IZ (Ingenieurtechnisches Zentralbüro Böhlen) air-jet fermenters with a reactor volume of 2200 m^3]

with respect to substrates in the broadest sense, and to pH, temperature, etc.), and the behavior of cells in the inner and outer circuits of the fermentation system.

Typical biomass concentrations in a reactor range from 20 – 50 kg of biomass dry matter per ton of fermenter content (medium), with a maximum of 150 kg/t. Standard separation techniques are employed (e.g., flotation, sedimentation, separation, centrifugation, decantation, filtration) depending on the physical properties of the microorganism cells and the suspen-

sion (density, size, floc diameter). The result of separation is a suspension containing 15 – 22 % dry matter. Further concentration to ca. 25 % is achieved by evaporation. The most common drying methods are spray, fluidized-bed, and freeze drying. The product is delivered to the consumer either as a powder or pelletized. Purification and further refinement (e.g., extraction) are also included in the overall process.

Control of the fermentation (i.e., growth) requires monitoring the pH, temperature, and oxygen and ion contents of the solution, as well as the CO_2 concentration in the exhaust air. To some extent, biosignals (e.g., levels of cytochrome c, NAD^+ – NADH, etc.), are also employed [28]. The type of control depends on the selected organism – substrate system, with possible types being run-off and real-time control.

Basic technology for SCP production is sized according to the availability of raw materials and the intended product output. Facilities designed for the production of Fermosin are illustrative of a typical large-scale plant (Figs. 1 and 2) [10, 29]; see also Table 1.

Figure 3. Cells of the production strain *Candida maltosa* on a droplet of petroleum distillate (original size ca. 3×6 µm)

In the Fermosin process, a highly productive strain of the yeast *Candida maltosa* (Fig. 3) is propagated continuously on a straight-run petroleum distillate (boiling range 240 – 360 °C) at 32 °C and pH 4.2, with a residence time of 5 h. The growth stage is followed by decantation (removal of 60 % of the process water, ca. 90 % of which is returned to the process), multistage separation (oil – water, biomass – water), evaporation, spray drying, and extraction (with a methanol – ethanol – water mixture). The main product is Fermosin (for quality information, see Table 6 and also Tables 10, 11, 12). Other products include a biolipid extract containing fatty acids, phosphatides, glycerides, sterols, and waxes [35], and a deparaffinized petroleum distillate, which can be used as a low-temperature diesel fuel.

Apart from the production of SCP in large industrial plants, attention should also be directed in the future to small, decentralized, village-level plants with high productivity. Such plants could satisfy localized feed requirements, and simultaneously exploit locally produced raw materials and industrial or agricultural waste (biogas, low-grade petroleum, waste methanol, distillery residues, and whey). They offer economic advantages because of savings in transport costs, potential local use of SCP production wastes (CO_2 in greenhouses, waste heat), and direct application of process effluent SCP (liquid feeding; for cost projections see Chap. 6). Opportunities for SCP production also exist in less developed regions. An example is a facility for utilization of the fruit from *Ceratonia siliqua* by the fungus *Aspergillus niger* [30]. Process steps involved in this case are hot-water extraction of the sugar, addition of ammonium sulfate and dihydrogenphosphate, batch fermentation, thickening in a vacuum rotary filter, and drying in a ring dryer. A 3 m^3 stirred-tank reactor is used, and the result is a storable product [30].

5. Products and Uses

The final product of an SCP process is biomass. Apart from proteins, which are the primary constituents, it contains nucleic acids, lipids, and carbohydrates (Table 6), as well as vitamins and coenzymes (Table 7). This gives rise to market possibilities beyond the original objective (Table 8).

Moisture, ash, and crude protein content are important parameters for characterizing the commercial product. A crude protein assay (nitrogen content×6.25) encompasses all nitrogen-containing compounds (proteins, nucleic acids, etc.); the reported ash value includes all mineral components as their oxides (Table 9). Protein concentrations range from 45 – 80 %. Apart from strain- and process-dependent differences, bacteria have higher crude protein values (65 –

85 %) than, for example yeasts because of higher nucleic acid concentrations (Table 6), which correlate directly with their high growth rate [15]. Protein quality is determined to a great extent by the concentrations and proportions of essential amino acids (Table 10).

If SCP is to be used as food, or even as feed, proof must be provided of its safety (e.g., lack of toxicity, mutagenicity, carcinogenicity, pathogenicity) and its organoleptic suitability. SCP can be used as animal feed without further treatment. However, it must always be mixed with energy-rich fodder (e.g., grain). Such mixtures should be well balanced from a nutritional–physiological and energetic standpoint. The material composition of microbial biomass assures proper balance in a mixture containing 5 – 20 mass % SCP.

Factors important with respect to the nutritional – physiological value of SCP include the true protein concentration, digestibility, protein efficiency ratio (PER), net protein utilization (NPU), and biological value (BV) (Table 11). The biological value is determined by the amino acid composition and the concentrations of essential amino acids. Even these factors are

[a] The digestibility of a protein may be expressed either as a "true digestibility," in which case allowance is made for fecal nitrogen loss on a protein-free diet, or as an "apparent digestibility," in which no such correction is made.

[b] $\mathrm{PER} = \mathrm{protein\,efficiency\,ratio} = \frac{\mathrm{weight\,gain}}{\mathrm{protein\,consumed}}$

[c] $\mathrm{NPU} = \mathrm{net\,protein\,utilization} = \frac{(\mathrm{body\,nitrogen\,of\,test\,group}) - (\mathrm{body\,nitrogen\,of\,group\,fed\,nonprotein\,diet})}{\mathrm{nitrogen\,consumed}}$

[d] BV = biological value = (resorbed nitrogen from food) − (urinary nitrogen − endogenous urinary nitrogen)

[e] +3 % methionine.

insufficient for total SCP evaluation, however. Quality guidelines and additional criteria (e.g., for such toxicologically relevant substances as heavy metals, benzopyrenes, and hydrocarbons, see Table 12), have been established by IUPAC and the Protein Advisory Group (PAG) of the United Nations Food and Agricultural Organization (FAO) [38].

In order to determine the nutritional – physiological value of biomass, experiments are conducted in stages according to established protocols. Laboratory animals (preferably rats) are used in the first stage and farm animals in the subsequent stages. These experiments are designed to monitor feed intake, nitrogen balance, and increase in live mass (see Table 13), as well as reproduction and fertility.

In principle, SCP can also be used directly in human nutrition. The value of the product is comparable to meat products because of its high protein content and favorable amino acid composition. However, this use of SCP requires that it also comply with other nutritional – physiological criteria [39, 40] (e.g., content of nucleic acids, fatty acids, and contaminants), that its formulation be appropriate, and that the costs be lower than those of rival plant products (e.g., soy protein).

6. Economic Aspects

The price of SCP varies from 260 to 1030 €/t (1993). For any given set of process parameters (see Table 14), production costs are a function mainly of the price of raw materials, energy, and plant. Process-dependent cost factors include substrate cost, operating expenses, and depreciation. Sample calculations are provided in Tables 15 and 16. Despite process-dependent differences, the cost of the substrate has the greatest influence on the profitability of an SCP process. This represents about one-third of the total cost if petroleum distillates are the carbon source, and

with other carbon sources it may approach one-half of the total [36]. The rate of consumption of raw materials, including technology-dependent losses, tends to be specific to a particular type of organism and process. Consequently, the choice of microorganisms and technology has a significant influence on product cost. Minimum costs attributable to biological substrate consumption alone are on the order of 150 €/t for petroleum distillate – yeast SCP and 400 €/t for methanol – bacterial SCP. For this reason, SCP prices below ca. 510 €/t are currently (1993) impossible to achieve.

Energy consumption also contributes significantly to operating costs. Energy is required for gas transfer, especially for supplying oxygen to the microorganisms (air compression), but also for cooling (withdrawal of biological process heat), sterilization (steam generation, especially in protected processes), and processing (drying). Oxygen consumption is coupled to substrate consumption, and both are in turn dependent on process design. The costs associated with biomass separation vary with biomass concentration in the fermentation medium and with the size of the biomass cells to be separated. (Because of their smaller cell size, the effort entailed in separating bacteria is substantially greater than that for yeasts.) Capital costs are determined by the demand for technical equipment, which depends on the number of process steps and the equipment layout, as well as by the size of the plant. For a given level of output, these factors decrease with increasing productivity of the process and the space – time yield of the fermenter, respectively. The most favor-

able scale economically for a large facility for converting nonreplenishable (fossil) raw materials lies between 50×10^3 and 300×10^3 t of dry matter per year [36].

An objective choice among various potential technologies, microorganisms, and process layouts is difficult because of the complexity of the process as a whole. It will almost certainly be a compromise, reached only after attempting to visualize potential processes in their optimum form on the basis of suitable evaluation criteria and biological and reaction engineering models that reflect current economic, technical, and physicochemical parameters.

Table 13. Fattening experiments with pigs and chickens [10] (pigs: fattening period 26 – 115 kg live mass; chickens: fattening period up to 56 d of life)

Relative	100	98	94	100

* DS = dry substance; LM = live mass; LMI = increase in live mass.

With regard to substrate requirements, a short residence time is advantageous because it is linked to low specific substrate and oxygen consumption. However, rapid growth also leads to lower concentrations of pure protein and higher concentrations of nucleic acids, which in turn impose greater demands for purification. On the other hand, at a given constant output, the reactor size requirement decreases with increasing productivity, reducing both investment costs and debt service. Figure 4 shows that when all the technological factors are considered, the economic optimum for the yeast – petroleum-distillate system does not coincide with the lowest level of biological oxygen consumption. Operating temperatures >45 °C are not economical for this particular process.

Figure 4. Dependence of fermentation costs (relative values) on specific oxygen consumption and process temperature [45]

A cost comparison alone is not sufficient for evaluating the efficiency of SCP as a source of fodder, or for comparing various single cell proteins with each other and with competing products. In fact, such a cost analysis gives a false picture. The products in question differ in their compositions, and these differences are strain- and process-specific, which in turn has an impact on feed value. The situation becomes clearer when comparisons are based not on SCP production costs, but rather on required expenditure for generating a unit of animal product, because this factor does not vary appreciably with respect to quality. The overall cost for a balanced feed ration then becomes an easily manageable stan-

A balanced feed ration must take into account all the factors that are of nutritional – physiological importance. Apart from crude protein content these include levels of amino acids, vitamins, and minerals, among others. In practice, particular attention is directed toward digestible crude protein, energy content, and content of the amino acids lysine, methionine, and cysteine [46]; see Table 17. Ration calculations show that for a given expenditure on SCP production, biomass with a higher lysine content – even if it has less crude protein and sulfur-containing amino acids – results in lower ration costs, and should be given priority. At an SCP price of 510 €/t, the ration price for the production of 1 t of pork from mixtures of SCP and wheat is 2 % lower for a biomass containing 48 g of lysine and 688.5 g of crude protein per kilogram of biomass dry matter than it is for a biomass with only 44 g of lysine but 731 g of crude protein per kilogram of biomass dry matter. A 10 % increase in the lysine content of a microbial biomass (corresponding to 1 g/100 g of protein) leads to a 2.5 % decrease in the price of the total ration. This explains the economic interest in high-lysine biomass products. It also sets realistic parameters on research into increasing the lysine content. In view of the limited prospects for success through genetic engineer-

Table 16. Relative prime costs for the production of SCP from petroleum distillates (percent of total prime costs for production)

Type of cost	Process stage					
	Fermentation and chemicals	Separation	Evaporation and drying	Extraction	Formulation and waste treatment	Total

ing it would appear advisable to invest more effort in supplementing food rations with microbially produced lysine.

7. Outlook

Biotechnologically produced protein must still demonstrate its ability to compete with protein produced agriculturally – which it is currently (1993) unable to do. Competitiveness with soybean, the most important agricultural protein feed, would be established only if soybean prices were to increase to about three times their current level (ca. 171 €/t in 1993). At present, the best opportunities for exploiting available technological know-how in the production of SCP are associated with decentralized plants that couple waste utilization with SCP production in a local setting [47]. However, future shortages of plant protein could make the industrial production of SCP viable.

The feed requirement of the EC is an indication of the potential involved here: over many years (1980 – 85) this group of countries has consumed an average of about 80×10^6 t/a of mixed feed with a mean crude protein content of 21 %, corresponding to 16.7×10^6 t/a of crude protein. The alternative use of a mixed feed containing 15 mass % SCP would require 12×10^6 t of SCP. Depending on the nature of the biomass, this is equivalent to between 6×10^6 and 8.2×10^6 t of microbial crude protein, representing 36 – 50 % of the total feed crude protein.

At an average production output of 100 000 t/a of biomass each, this would require 120 production facilities. The associated substrate requirement would be in the range of 12×10^6 t (*n*-alkanes) to 30×10^6 t (methanol), levels comparable to present world production figures for ammonia. This clearly illustrates that industrial production of SCP would entail a considerable restructuring of materials management, which could in turn be realized only over a long period of time.

1. Introduction

The manufacture of semifinished products and structural parts by the production and processing of metal melts has been known since ancient times. A second, less well-known technology has also developed, in which semifinished products and structural parts with near net shapes, or that are ready for installation, are manufactured from metal powders (Powder Metallurgy and Sintered Materials); often, metal melts are not involved in this manufacturing process.

Historical Aspects. The industrial production of metallic bodies (predominantly high-melting metals) by powder technology can be dated to the beginning of the nineteenth century [1]. The powder metallurgy (PM) manufacture of iron and steel articles began in about 1930. The first developments concerned sintered magnets (German Reichspatente 306772 and 679594). Porous iron bearings and machine parts made of sintered iron were first produced around 1935 [2], [3]. Production engineering advantages and lack of skilled labor for the machining work were the driving forces for this development [3]. The subsequent rapid development of iron and steel PM is due to many factors, which include

1) Reduction of machining
2) High raw material utilization
3) Low energy requirements
4) Large variety of geometrical shapes combined with narrow tolerances
5) Good reproducibility of geometrical – and mechanical – physical properties
6) Outstanding suitability for mass production

These advantages lead to a favorable cost situation in the mass production of mechanically stressed, geometrically complex structural parts with narrow tolerances. The development of the property profile can be illustrated by following the improvement in tensile strength since 1940 (Fig. 1) [4].

In addition to structural parts manufactured by pressing and sintering, PM ferrous semifinished products have been developed since ca. 1960. This required the parallel development of special PM processes and alloying techniques. As a result, very highly alloyed materials with outstanding properties have been obtained [5–14]. Forming techniques for structural parts with near net shapes have also undergone consider-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_185

able improvements and advances [15–22]. Great efforts are being made to develop an extensive range of composite structures [23–27].

Figure 1. Development of the tensile strength of sintered steel [4]

PM materials and parts made of sintered steel and iron are now used in all areas of daily life, as demonstrated by the following examples:

- Porous materials and parts for maintenance-free, self-lubricating bearings
- Porous stainless steels for filters and ventilation units in the chemical industry
- Medium-density low-alloy and stainless steels for inexpensive moldings for fittings, domestic and handicraft tools, locks, hardware items, automobile construction, and domestic appliances
- Medium-density alloys of pure iron, iron – silicon, and iron – phosphorus for magnetic applications
- High-density low-alloy steels for highly stressed parts in automobile construction (synchronizing rings, oil pump wheels, gear and transmission parts, valve drive parts, etc.)
- High-purity materials without residual porosity for electromagnetic applications
- Stainless steel tubes and profiled rods for process technology
- Creep-resistant steels without residual porosity for turbine construction
- Wear-resistant carbide tool steels for tool construction and components subject to wear in processing plants

Further developments and improvements in powder production (e.g., very fine powders with a high sintering activity), forming (e.g., metal injection molding), heat treatment (e.g., continuous belt sintering furnaces at $\leq 1300\,^{\circ}C$), and many other areas will expand the application range of PM products. These process technology developments are accompanied by intensive research activity [28].

Economic Aspects. Worldwide consumption of iron and steel powders in 1991 for PM products was approximately 420 000 t. North America accounted for ca. 170 000 t, Asia 130 000 t, and Western Europe 90 000 t. Structural parts made of sintered iron and steel are now used in nearly all areas of daily life. The consumption of PM structural parts in various industrial sectors is illustrated in Figure 2 for North America, Japan, and Europe. The overwhelming importance of the automobile industry as a consumer of PM components can be seen in Figure 3 [29]. In the United States about 11.1 kg, in Japan 6.2 kg, and in Western Europe about 4.7 kg of PM structural parts are used per automobile [30].

Definitions and Standards. A detailed summary of PM standards is given in [31]. According to DIN 30 900 the term powder metallurgy is defined as the "production of metallic powder and the fabrication of parts from this powder with or without the addition of nonmetallic powders by forming and sintering." Accordingly, the PM production process consists of three basic steps: preparation of the starting materials, densification, and consolidation by sintering.

In the metal-processing industry the expressions sintered iron and sintered steel are understood to mean semifinished products and structural parts that are made from unalloyed or alloyed iron powders by PM processes.

2. Iron and Steel Powders

2.1. Powder Production

A range of technologies are available for producing iron and steel powders that satisfy current high-quality requirements. The importance of individual techniques has changed during the course of development. In contrast to other PM

Figure 2. Consumption of PM iron and steel products in Japan, North America, and Western Europe according to area of use

products, mechanical comminution is not a primary process for the production of iron and steel powders.

2.1.1. Reduced Metal Powders

Reduced metal powder is produced from metal compounds by chemical reduction. Roller scale (oxide) or iron ore may be used as starting material for iron powder.

Pyron Process. The Pyron process enjoys a certain popularity in the United States. Roller scale (mainly Fe_3O_4), which is produced in rolling mills during the processing of unalloyed steels, is first ground and then freed of nonmagnetic constituents by using a magnetic separator. Common minor constituents such as manganese or silicon are simultaneously removed in the form of their nonmagnetic oxides. The puri-

Figure 3. Production of sintered steel and automobiles in the United States, Japan, and the Federal Republic of Germany

fied oxide powder is roasted in air and reduced in a stream of hydrogen at 870 – 1040 °C.

Grinding, followed by size classification, yields powder particles that are largely permeated by micropores of some µm in diameter (a characteristic of all reduced metal powders). Pyron powders have a relatively low apparent density of 2.3 – 2.5 g/cm^3, but as a rule can be easily densified [32], [33].

Sponge-Iron Powder. The Höganäs process (→ Iron) has become extremely important for the production of reduced metal powders [34–37]. The Höganäs process yields sponge-iron powder and still supplies about 40 % of the worldwide demand for iron powder, despite the success of atomization processes (Section 2.1.2). The production of sponge-iron powder is illustrated in Figure 4. Extremely pure magnetite ores (e.g., as found in Keruna, northern Sweden) are used as raw materials. The ore is comminuted, screened, and purified by using magnetic separators (a, d). A reduction mix of coke granules and calcium oxide is prepared in parallel (a – c). The beneficiated ore is packed into a retort (e, p) whose silicon carbide jacket is lined with a layer of the reduction mix. The retort also contains a central core of the reduction mix. Reduction is carried out over 24 – 40 h at 1050 – 1200°C. The following main reactions take place:

$$Fe_3O_4 + CO \rightarrow 3\ FeO + CO_2$$

$$FeO + CO \rightarrow Fe + CO_2$$

Reduction is controlled by the Boudouard equilibrium

$$CO_2 + C \rightleftharpoons 2\ CO$$

Desulfurization occurs during reduction, whereby the lime absorbs the sulfur and is carried out in order to improve the properties of the product. The energy required for reduction is generated in tunnel furnaces that are several hundred meters long (f).

The reduction product is a relatively strongly sintered crude sponge. Adhering slag is removed from the sponge, which is then processed into powder by repeated grinding, purification using magnetic separators, and screening (j – l). The crude powder is subjected to final reduction in an ammonia atmosphere in a continuous furnace (m). The reduction temperature must be sufficiently low (500 – 600 °C) to avoid resintering the powder particles. The sponge-iron powder product has an apparent density similar to that of Pyron powder. The pores in the powder particles are, however, coarser.

2.1.2. Atomized Powders

Pig-Iron Scale Process. Iron powder is obtained by atomization of a pig-iron melt containing ca. 3.5 % carbon, which is melted in a

Figure 4. Production of sponge-iron powder (with permission from Höganes)

cupola furnace [38], [39]. Air is injected under high pressure through an atomization nozzle onto the free-falling, liquid pig-iron jet. The pig-iron melt is broken up and solidifies into small droplets that are collected in water. Atomization leads to surface oxidation of the particles (oxygen content ca. 6 %). Reductive annealing with the optional addition of a reducing gas, converts the powder into a low-carbon, low-oxygen cake that is then ground. The powder is screened and attains its technological properties after final annealing. Its structure and pressing properties are very similar to those of sponge-iron powder.

The process is generally carried out in a modified form in which water under high pressure is used as atomization medium instead of air [38–41].

Water-Atomized Powders [42]. The technology of iron powder production is increasingly changing over to the water atomization process (Fig. 5), which uses iron scrap as starting material [43], [44]. The process steps are very similar to those of the pig-iron process, but more efficient electric arc furnaces had to be developed to reach the high melting points of low-carbon scrap iron. The atomized powders contain about 1.5 % oxygen. Dewatering (f) is followed by drying (g) and reduction under a protective gas (e.g., H_2 or NH_3). Unalloyed powders produced by this process have a relatively high apparent density combined with a good pressability. The content and size of slag particles are considerably lower than those of the previously discussed powder production methods. This is beneficial for the manufacture of high-strength structural parts as the inclusion of slag particles

Figure 5. Production of water-atomized iron powder (with permission from Höganäs)

in the product diminishes the toughness and near resistance properties.

Water atomization permits the production of high-alloy ferrous powders [e.g., the austenitic powders X3CrNiMo 17.13(AISI 316 L), X2CrNi 19.11 (AISI 304 L)]; the martensitic powder X10 Cr13 (AISI 410); and the ferritic powder X6Cr13 (AISI 430). High-speed steels and hard alloys with a high cobalt content (stellites) can also be subjected to water atomization. Postcomminution processes (e.g., the cold stream [45] and vacuum reduction processes [46]) often have to be employed in the case of high-alloy powders; they yield products with particularly low oxygen content [47]. Water atomization processes provide a substantially larger variation in particle shape, particle-size distribution and possible alloy states, compared to the other processes discussed thus far. The particle sizes can be reduced to $< 50\,\mu m$ by increasing the water pressure. Mean particle diameters of ca. $10\,\mu m$ are achieved on a production scale [48], [49]; these powders are produced for special purposes (e.g., metal injection molding).

Oil-Atomized Powders. In the water atomization of alloys with elements having an affinity for oxygen (e.g., Cr and Mn), increased oxygen uptake can cause problems. An attempt was therefore made to provide an effective remedy by using oil as the atomization medium instead of water [49–51]. The reduction in oxygen content was, however, offset by an increased carbon content, which had to be lowered by special annealing treatment. For reasons of cost, oil atomization has not gained general acceptance and is only of minor importance.

Gas-Atomized Powders. Inert gases (nitrogen, argon, and in rare cases, helium) can be used instead of liquid atomization media for the production of special powders. For cases in which the oxygen loading of the powders is particularly critical, atomization may also take place in vacuo. The principle of inert gas atomization is illustrated in Figure 6 [52]. The chemical composition of the powder remains essentially the same as in the melt. Subsequent reduction is no longer necessary to obtain lower oxygen content. The oxygen concentration and the amount

of ceram-ic inclusions (which may be due to slag formation and the melt feed system) can be kept low by special plant technology [52], [53]. Attempts have been made to use liquefied low-temperature gases as atomization media, but this technique has not yet proved economical [54].

Figure 6. Production of gas-atomized powders (with permission from H. C. Starck)
a) Induction tilting furnace; b) Tundish; c) Atomizer; d) Atomization chamber; e) Vacuum pumps; f) Powder collectors; g) Cyclone separator; h) Superfine filter; i) Ventilator

The predominantly spherical particle shape of gas-atomized powders and their high content of alloying elements mean that they cannot be processed by uniaxial pressing; special processing technologies are generally required. A great deal of effort is being expended on the optimization of gas atomization; a summary of the mechanisms of gas (and water) atomization is given in [42]. Standing ultrasonic waves are being used to promote the disintegration of the melt jet [55]. An attempt is also being made to produce special properties, in particular low oxygen content at small particle sizes, by combining gas atomization with water atomization [56–58].

2.1.3. Electrolytic Iron Powders

Extremely pure iron powders are required for special applications (e.g., materials and structural parts with special electromagnetic properties). One method of producing such powders is electrolytic deposition, in which iron plates are suspended as anodes in a bath of iron and ammonium sulfates. The iron powders are deposited on special steel cathodes at an anodic current density of about 215 A/m^2. The powder is dried, subjected to reductive annealing under hydrogen or ammonia, ground, screened, and then passed for further processing [59]. Electrolytic deposition yields a platelet-shaped powder.

2.1.4. Carbonyl Iron Powders

Another means of producing extremely pure iron powder is the carbonyl process, in which iron is reacted with carbon monoxide at $\leq$20 MPa and 200 °C to form iron pentacarbonyl, $Fe(CO)_5$, which is liquid under these conditions (→ Iron Compounds). The pressure is reduced, and $Fe(CO)_5$ vaporizes and decomposes at ca. 250 °C:

$$Fe(CO)_5 \rightarrow Fe + 5\,CO$$

Decomposition occurs from the vapor phase and results in spherical, generally very fine iron powder (diameter $<$10 µm) with a shell-like structure. The powder usually has a carbon content of 0.8 – 0.9 %. It also contains a relatively large amount of nitrogen and oxygen, and is therefore extremely hard. The carbon, nitrogen, and oxygen contents can be drastically reduced by reduction with hydrogen. The removal of these elements yields an extremely pure, very soft, spherical powder. Typical metallic impurities include nickel $<$ 100 ppm, chromium $<$ 150 ppm, molybdenum $<$ 20 ppm, silicon $<$ 10 ppm, and manganese $<$ 10 ppm.

This powder is used for electromagnetic applications because of its extremely high purity. The spherical grain shape makes it particularly suitable for metal injection molding [60–62].

2.2. Powder Properties

The metal powders are characterized by physical, chemical, and technological properties that influence processing and also determine the subsequent properties of materials and structural parts. These properties have to be considered in the choice of raw materials.

Physical Properties. The geometrical characteristics of powder particles are determined by the particle shape, particle size, and particle-size distribution. The particle shape depends largely on the production process and process parameters (Fig. 7). The particles are usually irregular; only in a few exceptional cases is the shape approximately spherical. In addition to the outer surface, powder particles also have internal surfaces, as in the case of porous sponge-iron powder (Fig. 7 A). Simplifying assumptions therefore generally have to be made when describing the particle geometry.

The *specific surface area* (m^2/g) is the sum of all (readily accessible) surfaces, referred to the mass of a given amount of powder. Since the sintering activity is reflected in the form of the particles, surface energy, the specific surface is very important. Suitable measurement methods include gas absorption (e.g., the BET method) [63] and are described elsewhere (→ Particle Size Analysis). The *size of powder particles* is generally defined as the diameter of a sphere enveloping the particle. It can be determined by screening methods, in which the mesh corresponds to the spherical powder particle diameter that can still just pass through the screen (ISO 4497). Sedimentation and diffraction methods using laser light or X-rays are also based on a spherical model of powder particle shape. Screening, sedimentation, and diffraction methods are used to determine the *particle-size distribution.* For further details of particle-size measurement, see → Particle Size Analysis and [32].

Often, a powder sample can be described sufficiently by means of an *average particle size.* Measurement with the Fisher subsieve sizer is based on the flow resistance exerted by a powder charge in an airstream. The measured flow resistance is compared to the resistance of a spherical charge with corresponding average powder particle diameters. The apparatus is very easy to assemble and simple to operate. Interpretation of the measurement requires care, however, since the powder sample may contain particles that deviate considerably from the measured, average particle diameter.

Description of the *particle shape* is substantially more difficult and is frequently limited to a qualitative, sometimes subjective, description. ISO 3252 defines nine different particle shapes.

1) Acicular → needle shaped
2) Angular → sharply edged or roughly polyhedral
3) Dendritic → of branched shapes
4) Fibrous → having the appearance of regularly or irregularly shaped threads
5) Flaky → plate-like
6) Granular → approximately equidimensional but of irregular shape
7) Irregular → lacking any symmetry
8) Nodular → of rounded irregular shape
9) Spheroidal → roughly spherical

More detailed, quantitative descriptions can be obtained only with the aid of statistical methods and quantitative image analysis [64].

The *hardness* of the powder, measured for example as the Vickers hardness, HV 0.1 plays an important role in subsequent processing. Hardness characterizes the plastic behavior of a material, and important conclusions about the behavior during forming can be obtained from this parameter. Alloying, thermal treatment, and strain hardening all contribute to the hardness of a metallic material, which thus reflects the overall production process. Under certain circumstances the strain hardening state is drastically influenced by screening and mixing after the powder has been annealed.

Chemical Properties. The chemical properties of the powders ultimately determine material specifications after processing and have a decisive influence on sintering behavior. A critical factor is whether the alloying elements are distributed homogeneously in the powder particles, or whether the powder is a mixture of different powdered elements or alloys. The principles of alloy formation are illustrated in Figure 8 [65]. Powders may be of four types:

1) Unalloyed powders consisting of particles of a single element.
2) Powder mixtures consisting of different elementary or alloy powders (Fig. 8 A). The final alloy is formed during the sintering process.
3) Partially alloyed powders consisting of alloying elements that are bound in elementary form (Fig. 8 B) or as master alloys (Fig. 8 C) and penetrate the base powder by diffusion. The alloy is formed during the sintering process.

Figure 7. Typical powder shapes obtained in various production processes
A) Sponge-iron powder; B) Water-atomized iron powder; C) Inert-gas-atomized powder; D) Carbonyl iron powder

4) Completely alloyed powders, in which all alloying elements are homogeneously distributed in the powder particles (Fig. 8 D). The alloy is formed during production of the powder.

Oxygen may be present as adsorbed water on the powder surface, as dissolved oxygen in the powder particle, or as chemically bound oxygen in the form of oxides in the powder. Excess oxygen can adversely affect the sintering behavior of the powder. The reaction of oxygen with carbon results in loss of carbon from the alloy, which is then no longer available for improving hardness in heat treatment. Reaction with oxygen renders metallic alloying elements ineffective in the metallurgical sense or can lead to formation of stable oxide skins on the particle surfaces that interfere with sintering by preventing diffusion.

The oxygen content can be measured as annealing loss under hydrogen (ISO 4491T2, 4491T3). The oxygen bound as nonreducible oxides (Al_2O_3, SiO_2, CaO, etc.) is not, however, included in this measurement. The total oxygen content can be measured by melting in a graphite crucible at $\geq$2000 °C. Oxygen is released by carbothermic reduction of the metal oxide and reacts with the carbon of the crucible to form carbon monoxide. The amount of carbon monoxide formed is determined by IR spectrometry (ISO 4491T4).

With regard to work safety, the potential health hazards and the tendency to self-ignition (pyrophoricity) should be kept in mind when handling metal powders [66], [67].

Technological Properties. Metal powders are characterized by technological parameters that describe the special behavior and properties of the powders during processing.

The *apparent density* describes the specific weight of a powder when it is poured under the action of gravity. It is therefore used for

the volumetric metering of powder into molds (ISO 3923).

Figure 8. Types of alloy formation
A) Powder Mixture of different elements or alloys; B) Alloy powder bonded to the base powder by diffusion processes; C) Powder mixture using a master alloy; D) Prealloyed powder

In the axial pressing technique the mold is generally filled by flow under the force of gravity. Flow behavior is characterized by a standard test in which the time taken for 50 g of powder to flow through a funnel is measured (*flow rate*) (ISO 4490). The flow rate is largely determined by the particle size and the particle-size distribution.

Compressibility is determined by using a standard round die that is filled under gravity. The density of the compact during pressing is measured as a function of a given force of pressing and describes the compaction behavior of the powder (ISO 3927).

Springback describes the elastic behavior of the powder compact after pressing and during ejection from the pressing die. It is thus a measure of the tendency of a powder metal compact to form cracks during ejection from the die. Springback is sometimes also measured as a function of the specific force of pressure (ISO 4492).

The *ejection friction* is a measure of the stress exerted on the die due to friction between the powder compact and the die wall. It provides information on die wear.

The *green strength* is measured in a bending test on samples of rectangular cross section and shows of the mechanical stability of powder compacts. It is used to evaluate the handling of compacts (ISO 3995).

The *dimensional change* of a powder compact during sintering is a particularly important parameter required for the design and dimensioning of dies. The dimensional change may be positive or negative, depending on the compaction state, alloying state, and sintering parameters (atmosphere, temperature, and time). Zero dimensional change is often desired. The dimensional change is defined as (ISO 4492)

$$\frac{L - L_0}{L_0}$$

where
L = dimension after sintering
L_0 = die dimension

3. Forming and Sintering

Forming and sintering can be carried out either consecutively or in a single process.

3.1. Forming

3.1.1. Gravity Sintering

Gravity sintering is the simplest forming process in powder metallurgy. Metal powder is poured into heat-resistant molds where it is sintered. The sintered article therefore adopts the geometry of the mold. The mold material must have sufficient thermal stability at the temperatures employed for sintering and must not react with the metal powder. These requirements mean that gravity sintering is rarely used for sintered iron and steel. Experiments on the sintering of stainless steel filters have been published [68]. In medical technology, similar methods are used for applying porous coatings to solid implant materials. The coating is said to improve adhesion of the implant to the bone tissue [69], [70].

3.1.2. Uniaxial Pressing

By far the largest amount of iron and steel powder is processed into moldings by uniaxial pressing. Before the shaping process the powder is conditioned, which comprises

1) Combining the alloying powder constituents
2) Blending and homogenizing the powder mixture
3) Incorporating a suitable lubricant

The purposes of these stages are to produce an optimum alloy, to obtain appropriate technological properties, and to establish homogeneous material and structural-part properties after sintering. The lubricant dramatically influences the technological properties of the powder. It has a temporary function and must be removed from the formed part by vaporization before sintering takes place. The choice of lubricant is thus a compromise between properties relevant for pressing and the vaporization behavior; the aim is to achieve maximum vaporization and optimum lubrication. Metallic soaps such as zinc stearate or lithium stearate may be used; they have very good lubricating action but leave a residue on vaporization.

The trend toward the use of stearic acid, paraffin, or microcrystalline waxes is increasing. These substances vaporize without leaving a residue but generally have a poorer lubricating action than metallic soaps [71].

The powder is metered under gravity from a storage container into a die whose base is closed by a lower punch. The powder column in the die is compacted by movement of the lower punch and an upper punch.

The powder compact is then ejected from the die. The pressing tool returns to the starting position and the process is repeated. Further details are given in [65], [72], and → Powder Metallurgy and Sintered Materials, Chap. 5.1.

A wide range of shapes (Fig. 9) can be produced by using suitably designed dies and punches [73]:

1) Nonrotationally symmetrical parts can be formed by suitably contouring the die
2) Multiple-height parts can be pressed by providing shoulders in the upper and lower punches
3) Differences in pressing height can be increased by using split punches, the individual punch elements being controlled separately
4) Within certain limits, undercuts can be produced by means of split dies [74], special press control devices are required for this purpose

The rapid development of microelectronics has given a substantial impetus to design in uniaxial pressing. Modern process computer technology and sophisticated hydraulic systems allow control of very complicated pressing tools incorporating multiply split punches [75] (multiplate adapter technique) [76]. This means that the quality of complicated formed parts has improved, and the geometrical limits on freedom of design have substantially broadened.

Figure 9. Sintered steel and iron parts with widely differing shapes produced by axial pressing (with permission from SMK)

The powder particles are assumed to exhibit an elastic – plastic behavior. Density gradients are formed in the powder compact due to friction between powder particles and between the powder charge and the tool surfaces. The density distribution in a nickel powder compact pressed from one direction is illustrated in Figure 10 and also applies to iron powders. Levels of equal density are thus roughly conical. Pressing from two directions is generally used in practice and produces a symmetrical, mirror-image density distribution. Consequently, undesirably high density gradients may occur in very long moldings. The ratio of the height of the part to its diameter or wall thickness has an important influence on the formation of density gradients. Density gradients can be avoided at a height – diameter ratio of ca. 2.5. Substantially

higher ratios can be achieved with parts that do not require a high mechanical strength. Density gradients lead to gradients in the pore structure of the sintered material and thus to gradients in its properties. Furthermore, parts may become distorted.

Figure 10. Density distribution in a cylindrical nickel powder compact pressed from the top only

The cohesion of powder particles in ductile iron powders is effected by mechanical forming of the powder particles. This leads to mutual anchorage in which adhesion forces become effective. The elastic – plastic properties of the material, the morphology of the powder particles, and the choice of lubricants play decisive roles with regard to compressibility. A compaction diagram for iron powders is illustrated in Figure 11. The compaction curves become asymptotic with increasing compacting pressure. The asymptotic value is less than the density of the corresponding compact material (i.e., the metal powders cannot be completely compacted). The reasons for this are the increasing friction between powder particles, the increasing contact area between powder particles, and the cold hardening of the powder. If powders are to be compressed to extremely high densities (e.g., for strength reasons), further densification can be achieved by using double pressing. The compact is first pressed and then subjected to intermediate annealing to reverse the cold hardening of the powder particles and promote the formation of initial metallurgical contacts between powder particles. The annealing temperature should be chosen such that recrystallization processes can take place in the powder, but alloying elements (particularly carbon) in the powder mixture do not dissolve. Annealing is followed by a second pressing step and a sintering step at high temperature.

Figure 11. Compaction diagram for iron powders
a) Water-atomized iron powder; b) Water-atomized prealloyed Fe – Mo powder; c) Sponge-iron powder

Computer methods (finite-element analysis) and sophisticated measuring techniques have been used to improve understanding of the processes occurring in uniaxial pressing in order to optimize the pressing procedure [77–79]. Such investigations may also serve to optimize tools with regard to the friction between the die wall and powder charge [80].

3.1.3. Cold Isostatic Pressing

Cold isostatic pressing overcomes the limitations of uniaxial pressing in the processing of slightly ductile materials and the production of very large parts. Here, compaction is effected by means of a liquid medium that acts on the powder from all directions. The resulting (quasi) hydrostatic pressure conditions give a substantially more favorable density distribution in the powder compact, thus allowing production of very large bodies with complicated shapes.

The powder is packed into a tight, elastic mold of similar shape to the desired end contour. The mold is closed and placed in the pressure medium. Densification results by raising the pressure at room temperature. The pressure is then reduced, and the mold removed from the pressure medium. The formed part is removed from its sheath and sintered.

In the wet-bag method the elastic mold is filled outside the press and closed. In the dry-bag

method the mold is a constituent part of the pressure chamber and the powder is packed directly into the mold. The dry-bag method permits a quasi-hydrostatic pressure loading and is therefore particularly suitable for cylindrical bodies.

Pressure vessels with diameters ≤ 2 m and heights ≤ 4 m are available. The pressures employed are ≤ 600 MPa [81], [82].

By using cores, hollow bodies of complicated geometries (e.g., with internal threads) can also be produced. Cold isostatic pressing is used to produce large, stainless steel filter candles for process engineering [83], semifinished products and near net shapes from high-speed steel, and cylinder liners for large diesel engines [81], [84].

Figure 12. Processing scheme for metal injection molding

3.1.4. Metal Injection Molding

Injection molding has only recently been employed for sintered iron and steel. This process combines the design freedom that is a feature of plastics technology with the material properties of high performance steels, thereby providing the designer with completely novel possibilities [17], [19], [85–87].

Metal injection molding (Fig. 12) is similar to the injection molding of thermoplasts or thermosets, except that molding is followed by further treatment. Very fine metal powders are homogeneously mixed with thermoplastic binders and plasticizers. To achieve good flowability and thereby ensure optimum processibility, spherical powders are preferred. Inert-gas-atomized powders are frequently employed. However, iron carbonyl powders are normally used for low-alloy steels.

The thermoplastic binder gives the material an injection-moldable consistency and binds together the metal powder particles in the green body. This adhesion is necessary since the powder particles are not deformed during injection molding, in contrast to the case in uniaxial pressing. The metal powder constitutes 50 – 70 vol % of the molding material. At processing temperature the material has a consistency similar to that of toothpaste; it is processed in reciprocating screw injection molding machines at 150 – 250 °C. The injection-molded parts possess all the typical geometrical features of the finished product but have a larger volume because of their binder content.

Most of the binder and plasticizer are then removed from the molding by thermal decomposition and vaporization. The green body is converted into a porous, sensitive, but still manipulable body. Binder residues must remain in the formed part until the first sintered contacts are formed in the subsequent sintering process.

Sintering may be carried out in conventional protective gas atmospheres or under vacuum. The individual powder particles coalesce, which results in a loss of porosity and decrease in volume of the body. Shrinkage is dimensionally uniform and between 10 and 17 %. The degree of shrinkage is governed by the proportion of binder and plasticizer in the feedstsock. Purely metallic parts with a low residual porosity (generally < 5 vol %) are obtained. Metal injection molding produces parts that are ready for installation or whose properties can be modified for special applications by means of secondary operations. Examples are shown in Figure 13.

Figure 13. Components produced by metal injection molding
A) Components for security locks; B) Parts made of low-alloy steel for automobile construction

Experience has shown that economical production is generally possible with an annual production of $\geq 100\,000$ parts. In special cases, smaller output may also be feasible. Metal injection molding can be used successfully in applications where

1) Expensive mechanical processing can be reduced
2) Materials are to be used that cannot be machined or can only be machined with difficulty
3) The processing of expensive materials is necessary (high material yield by recycling sprue residues)
4) Integrated construction methods are to be employed (fewer joining operations)

A wide range of alloys can be processed by this technique since it is not restricted by powder properties. It is especially useful for very hard powders. The process has been applied to

1) Low-alloy steels
2) Acid- and alkali-resistant steels
3) Cold work steels and high-speed steels
4) Iron based magnetic materials with Si, Co, or Ni as alloying elements
5) Materials with low thermal coefficients of expansion produced from Fe – Ni alloys

3.1.5. Powder Rolling

Powder rolling (roll compacting) is a continuous process for producing semifinished products (wires and strips) for electrical and magnetic applications. The powder is compacted between two rolls into endless wires and strips before passing through the sintering oven. Several annealing and rolling steps can also be performed in succession for postcompaction and modification of structural properties [88–90].

3.1.6. Slip Casting

Slip casting is a method adopted from ceramics technology. Powder is suspended in a suitable solvent to form a casting slip that is then poured into porous molds. Slip casting of iron and steel alloys is not of any great technical importance. However, attempts have been made to use this process for one-off and small-series runs for producing complicated parts made of high-quality materials [71], [91].

3.2. Sintering

Principles. The structure and properties of the material are established during sintering. F. Thümmler has defined sintering as follows: "Sintering is a thermally activated material transport process that results in intensification of particle contacts and/or in a change in porosity and pore geometry, with a decrease in free enthalpy. It may involve a liquid phase" [65]. The term "thermally activated processes" is understood to mean diffusion processes. The driving forces are surface tension in single-phase systems (pure iron and completely alloyed systems), as well as concentration differences in powder mixtures and partially alloyed powders.

Surface, grain boundary, and volume diffusion occur as material transport mechanisms in solid-state sintering. Viscous slip processes and rearrangements due to rotation of individual particles or collections of particles may also make a substantial contribution. In the case of liquid phases, the above sintering mechanisms are supplemented by capillary forces [92–94]. If liquid phases occur in completely alloyed powders during sintering, this is described as "supersolidus sintering" [95], [96].

Solid-state and liquid sintering are described in detail elsewhere (→ Powder Metallurgy and Sintered Materials, Chap. 6.1.). In general, three sintering stages are distinguished:

1) Growth of particle contacts and formation of metallurgical boundaries between the individual powder particles (shrinkage is slight)
2) Formation of a coherent pore skeleton (shrinkage increases)
3) Formation of isolated pores, pore contouring, and elimination of pores (further shrinkage occurs, ultimately resulting in complete densification [65])

Figure 14 shows the dimensional changes produced by sintering as a function of the compacting pressure for sintered iron materials under various process conditions.

Figure 14. Shrinkage behavior of sintered iron alloys a) Fe + 1.5 % Cu, 1.75 % Ni, 0.5 % Mo, 0.6 % C partially alloyed (1120 °C, 30 min, endogas); b) Sponge-iron powder, 0 % C (1120 °C, 30 min, 75 % N_2, 25 % H_2); c) Water-atomized iron powder, 0 % C (1120 °C, 30 min, 75 % N_2, 25 % H_2); d) Fe + 0.6 % P, 0 % C (1120 °C, 30 min, 75 % N_2, 25 % H_2)

Pure iron powders and iron – carbon alloys are sintered in the solid state. Liquid-phase sintering is often also employed to promote densification. Elements that melt below the sintering temperature or that form low-melting eutectics with iron (e.g., Cu and P) are added to the iron powder. The formation of liquid phases is often transient; they disappear due to the reaction of the melt with the solid component. In the case of iron – copper alloys, volume changes resulting from solution processes and the formation of diffusion porosity can be used to a limited extent to compensate for shrinkage [92], [97], [98]. Initial swelling is then often observed prior to shrinkage [17]. The control of liquid-phase sintering is substantially more difficult than solid-state sintering because wetting is sensitive to interference (caused, for example, by oxides on powder surfaces) [99–104].

Sintering Atmospheres. The protective gas atmospheres have substantial influence on sintering kinetics. Unsatisfactory control of the oxidation potential of the sintering atmosphere can result in oxidation of the powder. Oxide formation greatly inhibits sintering by preventing diffusion; elements with a high affinity for oxygen (e.g., Cr and Mn) are bound so that they can no longer perform their metallurgical functions. A high oxidation potential is generally due to a high content of residual water vapor in the sintering atmospheres. The dew point of the gas is used to evaluate the water content. The carbon balance of the material can also be greatly influenced by the protective gas atmosphere, which may have a carburizing (excess CO) or a decarburizing (excess H_2O or CO_2) action.

Besides preventing oxidation, the protective gas also reduces any oxides already present. Carbon monoxide and hydrogen are primarily responsible for reduction. Nitrogen has a neutral function, although the formation of nitride should be kept in mind (e.g., with stainless steels) [105]. Nitride can bind with the alloying element Cr resulting a loss of powder corrosion resistance.

Temperature also has a decisive influence on the effect of the gases. In industrial sintering furnaces, special attention should be paid to conditions in the heating and cooling zones. Oxidizing conditions are desired in the dewaxing zone, especially with continuous sintering furnaces, to ensure complete removal of the lubricants from the moldings [71], [106–108].

Protective gas mixtures consisting of 75 % hydrogen and 25 % nitrogen are produced by

decomposing ammonia. This and other N_2-H_2 ratios are also obtained by mixing pure nitrogen and hydrogen. Atmospheres of $CO-CO_2$ are generally prepared by partial or complete combustion of propane, natural gas, butane, fuel oil, gasoline, etc. The term endogas or exogas is used, depending on whether energy is supplied to or released by the protective gas during its production. Endogas is used to control the carbon balance of the materials; its composition varies: 30–50 % H_2, 18–25 % CO, 28–48 % N_2, ≤ 0.5 % CO_2, ≤ 0.5 % CH_4, and ≤ 0.5 % H_2O. The dew point is between 0 and ca. −20 °C [71].

Subatmospheric pressures are used in the production of high-speed steels, magnetic materials, and low-alloy steels. Reducing conditions generally prevail in a vacuum. Also, dissolved gases (e.g., O_2 and N_2) can be removed from soft magnetic materials. The oxidation potential in vacuo is substantially lower than in protective gas atmospheres [109].

Industrial Sintering Plants. The majority of moldings produced from sintered iron and steel are sintered in continuous belt or walking-beam furnaces (→ Powder Metallurgy and Sintered Materials).

In belt sintering furnaces the sintered material passes through the furnace at up to 1150 °C on a heat-resistant steel belt. Attempts are being made to construct belt furnaces with ceramic belts and muffles that can be operated at ≤ 1300 °C [110].

In walking-beam furnaces the sintered material is transported through the furnace in boats or trays by means of a moving-beam system. Sintering can be performed at higher temperatures (≤ 1350 °C). The protective gas flows around the heating elements (Mo or W wires). Such furnaces cannot be operated with carburizing atmospheres because of the risk of carbide formation, which would destroy the heating elements, and the further risk of decarburization of the sintered material.

In all sintering furnaces the lubricant is expelled from the compacts by vaporization and combustion in a preheating (dewaxing zone), which proceeds the high-temperature sintering zone. A water-cooled cooling zone follows the sintering zone.

Vacuum sintering plants are very often used for materials with special properties, such as high-speed steels. Although these furnaces operate batchwise, they are highly flexible with regard to process control. Combined operation under both a protective gas and reduced pressure is possible. Such sintering plants are extremely cost intensive and are therefore used only for high-grade materials. The use of vacuum sintering plants for low-alloy steels has, however, also been reported [108].

3.3. Consolidation Processes Involving Simultaneous Application of Pressure and Heat

3.3.1. Powder Forging

Uniaxial pressing and the double press–double sintering technique have their limits in terms of achievable material density. Material densification is further increased by sinter forging, in which the formed parts are sintered in continuous furnaces and finally postconsolidated (forged) at 700–1100 °C in tempered pressing tools that are similar in construction to the powder pressing tools. Tool temperatures are 150–350 °C. Forging can be carried out directly by utilizing the sintering heat, or after intermediate cooling and reheating in an induction furnace.

The time during which the formed parts come in contact with the relatively cold tool must be minimized to avoid freezing the pores in subsurface regions. Short handling times in the ambient atmosphere also help to protect the surfaces against excessive oxidation. These requirements necessitate a high degree of automation.

Materials produced by powder forging have high tensile strengths (ca. ≥ 1000 MPa) combined with high elongations at break of (≥ 10 %). Low-alloy steels containing manganese, chromium, nickel, molybdenum, and carbon as alloying elements (total content ≤ 3 %) are used. Unalloyed iron–carbon materials can also be processed. Powder forging is used for highly stressed parts such as clutch rings, synchronizing rings, connecting rods, and pocket chain wheels [23], [24], [110–113].

3.3.2. Hot Isostatic Pressing

Hot isostatic pressing is a subsequent development of cold isostatic pressing. The parts are normally consolidated at high temperature ($\leq 1500\,°C$) and high pressure ($\leq 100\,MPa$) in water-cooled pressure vessels (Fig. 15). More extreme operating parameters may be used for special applications. The units are generally equipped with a rapid cooling device to achieve short cycle times [114], [115]. The batch is generally assembled on a frame outside the unit, which is lifted into the pressure vessel. Inert gases (N_2, Ar, or He) are used as pressure medium. Production units with a batch diameter <150 cm and a batch height <370 cm are in operation.

Figure 15. A heated pressure vessel with a protective hood for hot isostatic pressing (with permission from ABB)
a) Closure; b) Insulation; c) Frame; d) Pressure vessel; e) Heater

The powder usually has to be packed into heat-resistant capsules that must be evacuated before closure. The capsules must:

1) Permit shrinkage of the powder without crack formation
2) Not exhibit excessive fold formation or prevent shrinkage at the edges
3) Not react excessively with the powder
4) Be easily removed from the formed part

In an alternative approach the pressure vessel is first evacuated to sinter the powder in vacuo until the pores are closed. Complete densification then takes place under relatively moderate pressures ($\leq 20\,MPa$). This variant can generally be used only with liquid-phase sintering alloy systems since a rapid closure of the pores occurs [20], [116–118]. Care should be taken to ensure that adverse reactions do not occur between the PM materials and impurities in the pressure medium. The use of carefully purified gases is essential [119], [120].

Finally, a process has been developed in the United States in which a quasi-hydrostatic pressure is exerted by an inert powder charge [21], [22].

Attempts are being made to optimize parameters by taking the densification mechanisms into account [121–124]. Because of the complex process technology, hot isostatic pressing is economically viable only for materials with extreme material properties. Properties can be obtained that are not accessible with melt metallurgy:

1) Segregation-free structure (no solidification processes)
2) Extremely homogeneous distribution of very fine-grained carbides in high-speed steels
3) Avoidance of fracture-initiating pores
4) Production of very large parts with near net shapes (e.g., gas turbine parts) that are manufactured from poorly processible, expensive materials

The main advantages of hot isostatically pressed materials are the reduction in the critical defect size and the more uniform property values [14], [123], [125], [126]. Hot isostatic pressing is used to process high-speed steels, tool steels, and heat-resistant steels for turbine construction that are highly mechanically, thermally, and corrosively stressed.

3.3.3. Extrusion

In special cases, ferrous powder is processed into semifinished products under high pressure at ca. 1000 °C by shaping nozzles. Pipes and profiled rods of corrosion-resistant steels are produced in this way for the petrochemical industry, desalination plants, furnaces, and industrial heat exchangers. Inert-gas-atomized powders are packed into sheet-metal capsules and compacted by cold isostatic pressing. Subsequent extrusion is carried out in ram extruders using silica as a lubricant [127–129]. High-

speed steels are also processed by this technique [130].

Figure 16. Schematic diagram of spray compacting (with permission from Mannesmann)
A) Production of bolts and washers; B) Production of tubes
a) Tundish; b) Gas atomizer; c) Particle injection; d) Spraying chamber; e) Product; f) Drive

3.3.4. Spray Compacting

Spray compacting is a more recent development. A melt is atomized by a gas jet into droplets, which however do not cool completely. Instead, the liquid or doughy droplets strike a substrate on which they solidify by rapid dissipation of heat. Compacts in the form of bolts, pins, tubes, or two-dimensional products frabricated from steel (Fig. 16) and other metal alloys can be produced in this way. The materials do not exhibit segregation and have a fine-grain microstructure, due to the rapid solidification of the melt droplets [131], [132].

3.3.5. High-Velocity Compacting

Many attempts have been made to subject a wide range of powders to extremely high pressure in order to obtain simultaneous compaction and sintering [133], [134]. Shock waves generated by detonation of explosives [135], pulsed magnetic fields [136], or highly accelerated projectiles [137] have been used. However, these methods are not employed to any great extent on an industrial scale.

4. Secondary Operations

Only in very few cases can PM parts be employed directly after sintering. As a rule, various refining processes also have to be carried out with the intention of modifying the geometrical, mechanico-physical, chemical, and possibly optical and decorative properties of the formed parts for their intended application.

Sizing. Geometrical tolerances of sintered parts are reduced by means of a sizing tool, similar to a powder pressing tool. Their subsurface regions are shaped slightly by means of a punch and thereby lightly compacted. Sizing can be confined to selected geometrical features or can cover the entire part. In the case of porous sintered bearings the topography of the surface is established while at the same time the tribological demands are considered [32], [71]. In the double press – double sintering technique, pressing is carried out after the first sintering stage with a view to obtain a substantially higher density. This is referred to as postcompaction (instead of sizing).

Machining. If specific tolerance ranges are exceeded due to process or material factors or if geometrical features cannot be obtained (nondemoldable undercuts, tool-damaging contours), machining operations (e.g., drilling, grinding, milling, honing, and threading) may be carried out. Chip-breaking additives (manganese sulfide, boron nitride) may be used to improve the machinability of the materials. These additives generally have no significant influence on strength properties [138–141].

Infiltration and Impregnation. The porosity of PM materials often interferes with their use. In the United States, sintered steels are often infiltrated with copper to increase their strength,

particularly the impact strength, and also to impart impermeability to both liquid and gaseous media. Lead infiltration is also performed for tribological reasons [142–144].

If sintered steels are to be case-hardened or galvanically coated, the porosity can be sealed with water glass. This prevents carburization in the interior of the material and interfering influences during electrodeposition, respectively [145]. Impregnation with plastics is also known. Sintered bearings are impregnated with oils and fats to give them a maintenance-free, lifetime lubrication [32].

Surface Treatment. The influences of porosity should be considered in the surface treatment of sintered metals. If necessary, these influences can be minimized by sealing.

Metallic coatings can be deposited electrolytically by galvanic processes (zinc, tin, cadmium, copper, nickel, and chromium). Cadmium is seldom used because of environmental problems. Nickel coatings are applied by chemical reaction in aqueous solutions. Some metals (e.g., zinc, chromium and aluminum) are applied to sintered metals by diffusion processes [146].

Coatings Applied from the Gaseous Phase. Steam treatment is an inexpensive, widely employed technique for producing corrosion-resistant Fe_3O_4 coatings on sintered iron and steel. The sintered parts are treated for ca. 2 h in a saturated steam atmosphere at ca. 550 °C, resulting in the formation of a dense, blue-black Fe_3O_4 layer. Steam treatment is sometimes performed at the same time as the tempering treatment after hardening [147], [148]. Steam treatment can also be used to a certain extent to close porosity.

Gas nitriding, plasma nitriding, and nitrocarburizing can be carried out to improve wear resistance if the porosity has already substantially decreased [149–151].

Surface Strengthening. As in the case of melt metallurgy materials, the mechanical properties (particularly dynamic properties) of sintered steels can be improved by the generation of compressive forces in subsurface regions. Surface strengthening can be achieved by surface rolling or shot peening [151–155].

Surface Remelting. Attempts have been made to strengthen sintered steel by using high-energy laser beams for remelting. Remelting leads to a completely densified surface layer up to 1 mm thick. This process may be suitable for providing sintered steel parts with extremely strong surfaces in localized areas [156].

Heat Treatment. Sintered steels are heat treated to obtain specific strength properties. The end result is influenced by the alloy composition, the atmosphere, and temperature control. The porosity must be considered if heating is accompanied by carburizing or nitrocarburizing treatment. To prevent complete carburizing with case hardening, the porosity may have to be sealed [145], [157–160].

Joining of Sintered Iron and Steel. Solid joints between parts made of sintered steel or between parts made of sintered steel and melt metallurgical materials are used as positive-, nonpositive-, and material-locking joints. A wide range of methods is available for material-locking joints. All inert-gas welding processes may be used. Recent developments have made uniaxially pressed materials accessible to electron-beam and laser welding [156], [161]. Direct-current path resistance welding is a very elegant method, to increase the local current density at the joining site; hump-shaped projections can be produced on the sintered part with specially designed tools [25], [162].

Joints by brazing are difficult to produce in porous sintered steels since the pores may absorb the brazer due to capillary forces. The brazer should therefore be carefully selected to suit the application [26], [27], [163]. Recent developments have been aimed at producing joints by means of diffusion processes during sintering [163], [164].

Frictional welding is also used. The parts to be joined are pressed together and moved relative to each other. The resulting frictional heat is utilized to produce the weld joint [165], [166].

5. Strength Properties

Widely differing structures of sintered steels are formed, depending on the choice of raw material, alloy composition, compaction and sintering processes, and secondary operations. The structures of six arbitrarily selected materials having densities between 6.9 and 7.4 g/cm^3 give some idea of possible microstructures (Fig. 17).

Figure 17. Microstructure of six PM alloys
A) Fe – C; B) Fe – Cu – C; C) Fe – Cu – P – C; D) Fe – Cu – Ni – Mo – C; E) Fe – C; F) Fe – Cr – Ni – Mo (AISI 316 L)
A – D: Die pressed; E, F: Injection molded

A comprehensive collection of structure photographs of PM materials is given in [167]. The structure – property relationships of fully dense sintered materials are the same as those of melt metallurgical materials. Discussion is therefore limited to the special relationships applying to uniaxially pressed materials, in which porosity is the primary influencing factor. The special effects of alloying elements on strength occur only at relatively high densities.

Figure 18. Schematic diagram showing the relationship between the strength and density of sintered steels
a) Tensile strength; b) Bending fatigue limit; c) Elongation; d) Impact strength

An analytical description of the relationship between porosity and mechanical properties is extremely difficult because of the formation of complex three-dimensional stress states [168–170]. Most current knowledge is based on empirical results.

Figure 19. Tensile strength as a function of elongation for various sintered steel alloys (test method ISO/DIS 6892, specimen ISO/DP 2740)

The relationships between material density and strength properties are shown in Figure 18. Tensile strength is a linear function of density [65], but the bending fatigue limit and elongation at break increase disproportionately at high material densities. These relationships must always be taken into account in selecting materials. The tensile strength, 0.2 % yield

strength, and impact strength are shown for some important alloy systems in Figures 192021, respectively. The variations are due to variations in the alloy composition, the pressing and sintering conditions, and the final heat treatment conditions. These diagrams clearly illustrate the widely varying properties of uniaxially pressed sintered steels. DIN 30 912 specifies minimum strength values for standard sintered steels.

Figure 20. Yield strength as a function of elongation for various sintered steel alloys (test method ISO/DIS 6892, specimen ISO/DP 2740/1973)

Figure 21. Impact strength as a function of elongation for various sintered steel alloys (test method ISO/DIS 140.4, specimen ISO/DP 5754)

Continuous improvements in the strength of uniaxially pressed sintered steels mean that they can now also be used for dynamically highly stressed parts. This development has been accompanied by detailed investigations of strength and fracture behavior under vibratory stress. Under certain conditions, sintered steels containing the alloying elements copper, nickel, carbon, and phosphorus have fatigue strengths and fracture-mechanical values equivalent to those of compact steels and cast iron containing spheroidal graphite. This behavior is attributed to the crack-delaying action of the pores and the resultant notch insensitivity. Subsequent surface strengthening and heat treatment (e.g., nitrocarburizing) substantially improve the fatigue strength. The measured values provide the basis for fatigue strength dimensioning of PM parts [171–176]. This knowledge has permitted uniaxially pressed materials to be incorporated in critical components used for automobile construction. Sinter-forged connecting rods have been manufactured for a fairly long time in prototype-size and small-batch production runs. In the United States and Japan they have already been used in large-scale engine production. Developmental work is being carried out worldwide on "joined camshafts" with cams made from PM steel. Relatively expensive sintered high-alloy cams are also being mass produced. Intensive development is being carried out in cheaper, sintered, low-alloy cams.

Skeletal muscle relaxant drugs (muscle relaxants) are used in a variety of clinical situations. Choice of the individual agent is made with regard to its mechanism of action and its intended use [1–4].

Figure 1. A schematic showing a longitudinal section of a neuromuscular junction (motor endplate)
a) Schwann cell; b) Axon terminal in synaptic trough; c) Axoplasm; d) Myelin sheath; e) Sarcolemma; f) Sarcoplasm; g) Muscle cell nucleus; h) Myofibrils

1. Peripherally Acting Muscle Relaxants

Neuromuscular blocking agents are typically administered intravenously in hospitalized patients and at usual therapeutic doses; they are devoid of central effects including analgesic activity. Their site of action resides in the periphery at specialized receptors for the neurotransmitter, acetylcholine (ACh). At the motor nerve terminal, the impulse releases minute amounts of ACh (ca. 10^{-17} M) from intraneuronal storage vesicles in a Ca^{2+}-dependent process. ACh diffuses across a junction (synapse) to its receptor (the motor endplate) on skeletal muscle to form a receptor complex that opens channels in the cell membrane. This in turn, increases the permeability of the endplate membrane to sodium and potassium ions. The released ACh is rapidly inactivated (hydrolyzed) by acetylcholinesterase, an enzyme that is localized in high concentration in the vicinity of the motor endplate. A schematic diagram of a neuromuscular junction illustrating the motor endplate can be found in Figure 1.

If sufficient ionic sodium is conducted into these cells, a wave of membrane depolarization (action potential) is generated away from the endplate. Transmission of the action potential along the surface of the membrane of the muscle cell and the intracellular release of calcium ions from the sarcoplasmic reticulum leads to muscular contraction. Calcium regulates the contractile process, and adenosine triphosphate is the cellular energy source.

Neuromuscular blocking agents are principally used as adjuncts in surgical anesthesia to obtain satisfactory muscle relaxation, especially of the abdomen, which allows reduced doses of the anesthetic. They also may be administered for orthopedic and other procedures to facilitate muscular manipulation. They may be used during electroshock therapy to prevent bone fractures or compression fractures of the spinal column. Tubocurarine may also be employed in the diagnosis of myesthenia gravis.

The degree of muscle relaxation depends on the dose. The onset of action is rapid, and the sensitivity of muscles to peripheral muscle relaxants varies as a function of the size of the muscle

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and depends on whether the muscle is physiologically fast or slow. The muscles of the eye and face are the first to be paralyzed, followed by the muscles of the neck, larynx, and pharynx. The subsequent paralysis of the extremities and abdominal muscles causes loss of reflex muscular contractions. Only then does paralysis of the intercostal muscles and diaphragm ensue while consciousness is maintained.

1.1. Nondepolarizing Drugs (Competitive Neuromuscular Blocking Drugs)

The curare alkaloids represent the prototypic competitive neuromuscular blocking agents. Curare has been used on arrow tips for hundreds of years by native South Americans to kill animals for food. Death results from muscular paralysis. The mechanism of action of curare was first unraveled in the nineteenth century by Claude Bernard. Tubocurarine and other competitive neuromuscular blocking agents bind to the postjunctional motor endplate receptor making it insensitive to ACh. Since magnesium ions have a direct depressant effect on skeletal muscle, the dose required for neuromuscular blockade is reduced when plasma magnesium concentration is elevated.

These drugs can be competitively antagonized by inhibitors of acetylcholinesterase, such as neostigmine or edrophonium chloride, that increase the concentration of ACh in the motor endplate region. These acetylcholinesterase inhibitors may slow the heart and stimulate secretions; this may be controlled by atropine. They should be used with caution in asthmatics or patients with bronchoconstriction.

Alcuronium dichloride [*15180-03-7*], 4,4′-didemethyl-4,4′-di-2-propenyltoxiferinium dichloride, $C_{44}H_{50}Cl_2N_4O_2$, M_r 737.81, *mp* 85 – 90 °C. Prepared by either (1) reaction of the non-indole nitrogen of Wieland – Gumlich aldehyde with allyl chloride and dimerization to the diallyl toxiferene chloride or (2) dimerization of Wieland – Gumlich aldehyde to nortoxiferene and subsequent quaternization with allyl chloride [5].

Alcuronium dichloride has a short duration of action (15 – 20 min) and produces less blockade of autonomic ganglia and less histamine release than *d*-tubocurarine. Thus, it produces little or no bronchoconstriction or decrease in blood pressure. Its paralytic effects are intensified by the inhalation anesthetic, halothane.

Trade Names. Alloferin, Toxiferin (Roche).

Atracurium besylate [*64228-81-5*], 2, 2′-[1,5-pentanediylbis[oxy(3-oxo-3, 1-propanediyl)]] bis[1-[3, 4-dimethoxyphenyl)methyl]-1, 2, 3, 4-tetrahydro-6, 7-dimethoxy-2-methylisoquinolinium] dibenzenesulfonate, $C_{65}H_{82}N_2O_{18}S_2$, M_r 1243.5, *mp* 85 – 90 °C. The "reversed ester analogue of Doxcurium" is prepared by Bischler–Napieralski cyclization and sodium borohydride reduction to the 1,2,3,4-tetrahydroisoquinoline followed by Michael-type addition to the bisacrylate ester and alkylation with methyl benzenesulfonate [6].

Complete recovery from atracurium besylate takes ca. 30 min but might be longer under halothane anesthesia. It produces less blockade of autonomic ganglia than alcuronium dichloride with minimal histamine release. When the recommended dose is exceeded, moderate histamine release and a significant fall in blood pressure have been observed.

Trade Name. Tracrium (Wellcome).

Doxacurium chloride [*106819-53-8*], *trans, -trans*, 2, 2′-[dimethylene-bis-(carbonyloxytrimethyl-ene)-bis-(1, 2, 3, 4-tetrahydro-6,7,8-trimethoxy-2-methyl-1-(3, 4, 5-trimethoxybenzyl)isoquinolinium] dichloride, $C_{56}H_{80}Cl_2N_2O_{16}$, M_r 1108.16. Prepared by reaction of *trans-N*-3-hydroxypropyl-5′,8-dimethoxyaudanosiunium chloride with succinyl chloride [7] (see above).

Doxacurium chloride is a long-acting agent with considerable variability in duration between patients. Its duration is more prolonged in the elderly. The time required for 25 % recovery is highly dose-dependent and may be as long as 160 min after an initial 0.08 mg intravenous dose. Doxacurium chloride does not promote the release of histamine or affect cardiovascular parameters, is not metabolized, and is excreted unchanged in urine and bile. Its paralytic effects are intensified by the inhalation anesthetics, halothane, isoflurane, and enthrane.

Trade Name. Nuromax (Wellcome).

Fazadinium bromide [*49564-56-9*], 1,1′-azobis[3-methyl-2-phenylimidazo [1,2-α] pyridinium] dibromide, $C_{28}H_{24}Br_2N_6$, M_r 604.35, *mp* 218 – 220 °C. Prepared by heating 2-(2-acetylhydrazino)pyridine and 2-bromopropiophenone, hydrolyzing in 24 % hydrobromic acid, and oxidizing with aqueous bromine [8].

Fazadinium bromide has a rapid onset of action and is completely eliminated in patients with compromised renal function.

Trade Name. Fazodon (Robbins).

Gallamine triethiodide [*65-29-2*], 1,2,3-tris(2-triethylammonium ethoxy)benzene triiodide, $C_{30}H_{60}I_3N_3O_3$, M_r 891.54, *mp* 152 – 153 °C. Prepared by reaction of pyrogallol with diethylaminoethyl chloride and subsequent alkylation with ethyl iodide [9].

Gallamine triethiodide produces immediate paralysis lasting ca. 30 min after intravenous administration. It does not cause bronchoconstriction or release of histamine and does not affect autonomic ganglia. Since it is excreted unchanged by the kidneys, its plasma clearance is decreased in renal impairment. Its paralytic effects are intensified by diethyl ether or methoxyflurane.

Trade Names. Flaxedil (Specia, May & Baker, Lederle, Rhône-Poulenc), Relaxan (Gea), Tricuran (Deutsches Hydrierwerk).

Metocurine iodide [*7601-55-0*], dimethyltubocurarine iodide, 6,6′,7′,12′-tetramethoxy-2,2,2′,2′-tetramethyltubocuraranium diiodide, $C_{40}H_{48}I_2N_2O_6$, M_r 906.63, *mp* 257 – 267 °C. Prepared by reaction of tubocurarine with methyl iodide.

Metocurine iodide possesses similar pharmacologic properties to *d*-tubocurarine but is two to three times more potent. Thus, it should be used

with caution as an anesthetic adjunct. It does not produce the autonomic ganglionic blockade caused by *d*-tubocurarine.

Trade Name. Metubine iodide (Lilly).

Pancuronium bromide [*15500-66-0*], 1,1′-[3,17-bis(acetoxy)-androstane-2,16-diyl] bis [1-methylpiperidinium] dibromide, $C_{35}H_{60}Br_2N_2O_4$, M_r 732.68, *mp* 212 – 215 °C. Prepared by reaction of 2α, 3α: 16α, 17α-diepoxy-17β-acetoxy-5α-androstane with piperidine, and subsequent alkylation with methyl bromide [10].

Pancuronium bromide is approximately five times more potent than *d*-tubocurarine. It has minimal effects on the circulatory system and produces little histamine release or hormonal action. Complete recovery from pancuronium bromide takes ca. 65 min but this might be longer under halothane, enthrane, or isoflurane anesthesia. It should be used with caution in patients receiving chronic tricyclic antidepressant therapy because of a potential risk of ventricular arrhythmias.

Trade Names. Mioblock, Pavulon (Organon).

Pipecuronium bromide [*52212-02-9*], pipecurium bromide, 4,4′-[3,17-bis(acetoxy)androstane-2,16-diyl]bis(1,1-dimethylpiperazinium) dibromide dihydrate, $C_{35}H_{62}Br_2N_4O_4 \cdot 2H_2O$, M_r 787.77, *mp* 262 – 264 °C. Prepared by reaction of 2α, 3α: 16α, 17α-diepoxy-17β-acetoxy-5α-androstane with piperazine and subsequent alkylation with methyl bromide [11].

Pipecuronium bromide is a long-acting agent with an onset and duration similar to those of pancuronium bromide. Since it is eliminated primarily unchanged by the kidneys, its clinical duration is prolonged in patients with impaired renal function.

Trade Name. Arduan (Gedeon Richter, Organon).

Tubocurarine chloride [*57-94-3*], *d*-tubocurarine chloride, 7′,12′-dihydroxy-6,6′-dimethoxy-2,2′,2′-trimethyltubocuraranium chloride hydrochloride, $C_{37}H_{42}Cl_2N_2O_6$, M_r 681.66, *mp* 274 – 275 °C. Prepared by monomethylation of tubocurine [12].

Tubocurarine chloride has a duration of action of ca. 30 min. It should be administered intravenously by slow injection (ca. 1.5 min). Its potency is increased with more rapid rates of administration. Its paralytic effects are intensified by diethyl ether, halothane, isoflurane, and enthrane. Potency is expressed as units: 3 mg tubocurarine chloride is equivalent to 20 units. Since it releases histamine and clinical doses block autonomic ganglia it has a liability for hypotension and tachycardia.

Trade Names. (*d*-Form) Delacuratine (Squibb), Intocostrin-T (Squibb), Jexin (Duncan Flockhart), Tubadil (Endo), Tubarine (Burroughs Wellcome), Tubocurarine Chloride (Abbott, Lilly, Squibb).

Vecuronium bromide [*50700-72-6*], 1-[3,17-bis(acetyloxy)-2-(1-piperidinyl)androstan-16-yl]-1-methylpiperidinium bromide, $C_{34}H_{57}BrN_2O_4$, M_r 637.75, *mp* 227 – 229 °C. Prepared by reaction of 2α,3α: 16α,17α - diepoxy - 17β - acetoxy - 5α - androstane with piperidine and subsequent alkylation with methyl bromide [10].

Vecuronium bromide is about one-third more potent than pancuronium. Complete recovery from vecuronium bromide takes ca. 45 – 65 min but this might be longer under halothane, enthrane, or isoflurane anesthesia. It has less effect on the circulatory system than pancuronium and produces little histamine release or hormonal action.

Trade Name. Norcuron (Organon).

1.2. Depolarizing Relaxants

Depolarizing agents produce a persistent depolarizing effect at the motor endplate that is similar to that of ACh (phase I block), followed by a secondary nondepolarizing block (phase II block). The initial depolarization results in transient muscular twitching, followed by flaccid paralysis due to the blockade of neuromuscular transmission. In contrast to the competitive neuromuscular blocking drugs, administration of acetylcholinesterase inhibitors does not reverse motor paralysis and may even intensify it if given shortly after the depolarizing block.

The depolarizing agents are not degraded by acetylcholinesterase leading to their accumulation at the motor endplate. When increasing doses of these drugs are continuously administered, the motor endplate gradually repolarizes due to receptor desensitization. This phase II nondepolarizing block may now be reversed by the administration of an acetylcholinesterase inhibitor. Reversal should not be attempted unless (1) a peripheral nerve stimulator is used to confirm that the block is of the nondepolarizing type and (2) enough time has elapsed to permit hydrolysis of the agent by plasma pseudocholinesterase. Administration of fluorinated hydrocarbons increases the incidence of conversion from phase I to phase II.

Decamethonium bromide [*541-22-0*], decamethylenebis(trimethylammonium) dibromide, $C_{16}H_{38}Br_2N_2$, M_r 418.36, *mp* 268 – 270 °C. Prepared by reaction of 1,10-dibromodecane with trimethylamine in a sealed tube [13].

Decamethonium bromide is not appreciably metabolized and is mainly excreted by the kidneys. The acetylcholinesterase inhibitor, neostigmine, does not reverse its effect but the ganglion blocker, pentamethonium iodide, usually does. The mechanism of action of decamethonium changes after 20 – 30 min (phase II block), and neostigmine becomes an antagonist. Decamethonium bromide is no longer marketed in the United States.

Trade Name. Syncurine (Burroughs Wellcome).

Hexafluorenium bromide [*317-52-2*], hexamethylenebis(9-fluorenyldimethylammonium bromide), $C_{36}H_{42}Br_2N_2$, M_r 662.59, *mp* 188 – 189 °C. Prepared by reaction of 9-bromofluorene with dimethylamine and subsequent reaction with 1,6-dibromohexane [14].

Hexafluorenium bromide is a plasma cholinesterase inhibitor that is used in combination with succinylcholine chloride (see below). It prevents the muscular twitches induced by succinylcholine chloride.

Trade Name. Mylaxen (Wallace).

Succinylcholine chloride [*71-27-2*], suxamethonium chloride, 2,2′-[(1,4-dioxo-1,4-butanediyl)bis(oxy)]bis[*N,N,N*-trimethylethanaminium] dichloride, $C_{14}H_{30}Cl_2N_2O_4$, M_r 361.30, *mp* 190 °C. Prepared by reaction of ethylene bromohydrin with succinic acid and subsequent reaction with trimethylamine in a sealed tube [15]. It can also be prepared in one step from succinic anhydride and choline chloride [16].

Succinylcholine chloride has a rapid onset and short duration of action (5 – 10 min). It is rapidly inactivated by plasma pseudocholinesterase to form succinylmonocholine which is ultimately reduced to succinic acid and choline. If succinylcholine is given over a long period, the neuromuscular block may change to a phase II block which may be antagonized by neostigmine.

Trade Names. Anectine chloride (Burroughs Wellcome), Lysthenon (Chemie Linz), Midarine (Burroughs Wellcome), Quelicin chloride (Abbott), Scoline (Duncan Flockhart), Succicuran (Deutsches Hydrierwerk), Succinyl-Asta (Asta-Degussa), Succostrin chloride (Squibb-Marsam).

1.3. Agents Acting Directly on Skeletal Muscle

Dantrolene and the cinchona alkaloids, including quinine, exert a direct effect on skeletal muscle excitability. They are used to reduce muscle tone rather than to induce paralysis.

Dantrolene sodium [*14663-23-1*], 1-[[5-(4-nitrophenyl)furfurylidene]amino] hydantoin, $C_{14}H_{10}N_4O_5Na$, M_r 314.56, *mp* 229 – 231 °C. Prepared by coupling 4-nitrophenyldiazonium chloride with furfural and subsequent reaction with 1-aminohydantoin [17].

Dantrolene sodium reduces muscle tone by interfering with the release of ionic calcium from the sarcoplasmic reticulum [18]. Since this is more pronounced in fast muscle fibers, it has a preferential effect on reflex tone. The drug is administered orally for clinical spasticity but is of limited benefit in chronic spasticity because of side-effects, including drowsiness, dizziness, and weakness. It may be administered orally or intravenously to sensitive individuals to prevent or manage signs of malignant hyperthermia induced by neuromuscular blocking drugs or anesthetics during surgery. Dantrolene has a potential for hepatotoxicity.

Trade Names. Dantamicrin (Röhm Pharma), Dantrium (Norwich Eaton).

Quinine sulfate [*804-63-7*], 6′-methoxycinchonan-9-ol sulfate, $2C_{20}H_{24}N_2O_2 \cdot H_2SO_4$, M_r 746.93. It can be isolated from Cinchona bark, however, natural product synthesis has been reported by Woodward and others [19], [20].

Quinine sulfate has a complex action on skeletal muscle that includes a curare-like effect on the motor endplate and a direct reduction of tonus by altering intracellular distribution of ionic calcium. It is used clinically in the prevention and treatment of nocturnal recumbency leg cramps and in the treatment of myotonia congenita. It is well absorbed after oral administration. Quinine should not be given to patients with myesthenia gravis or to patients who have received neuromuscular blocking drugs.

Trade Names. Legatrin (Scholl, Inc.), Quin-260 (Major), Quinamm (Merrell Dow), Quine (Reid-Rowell), Quinine sulfate (Lilly), Quinite (Reid-Rowell).

2. Centrally Acting Muscle Relaxants

In contrast to the peripherally acting neuromuscular blocking drugs, the muscle relaxants acting on the central nervous system (CNS) are prescribed to outpatients for acute muscle spasms, as well as for the treatment of chronic spasticity. *Acute muscular spasms* are induced by reflexes caused by local pathology (e.g., inflammation of the muscles and/or joints, local trauma) or

by sprains and strains. An acute spasm is usually localized to a particular muscle or muscle group, is self-limiting, and benefits from pharmacotherapy, bed rest, and adjunctive physical therapy.

Chronic neurological spasticity, however, refers to a specific disorder of muscle tone which accompanies upper motor lesions anywhere from the cerebral cortex to the spinal cord. This disorder results from neurological diseases including cerebral palsy, multiple sclerosis, spinal cord injury, and stroke. Spasticity consists of a state of muscle hypertonicity, i.e., an increase of normal muscle tone or resistance to stretching; an intact spinal stretch reflex arc (stretch receptors, afferent nerve, spinal cord centers, motor nerve; → Neuropharmacology, Chap. 3.2.1.) is essential. Excessive muscular tone or constant state of muscular contraction may be present even when the patient is at rest but worsens during voluntary motion. This is due to excessively active reflex contractions whenever the patient stretches a muscle. In severe cases, the reflex contraction may spread, or radiate up and/or down the spinal cord so that the movement of a single limb produces involuntary contraction of the muscles of other extremities, or can even involve the head and neck. *Cerebral spasticity* results from a loss of descending inhibition or from uncontrolled activity in bulbospinal pathways regulating the reflex arc. However, *spinal spasticity* results from the loss of supraspinal inhibitory control of flexor withdrawal reflexes.

2.1. Treatment of Acute Muscle Spasms

A number of drugs are used to relieve locally occurring skeletal muscle spasms. While some of these agents have spinal and/or supraspinal interneuronal blocking properties, many of them produce sedation at therapeutic doses. The mechanism responsible for their clinical effects, however, is unclear. With the exception of diazepam, these agents are not used for the treatment of chronic neurological spasticity. They are administered as part of a regimen of bed rest and physical rehabilitation for painful musculoskeletal conditions.

Carisoprodol [*78-44-4*], *N*-isopropyl-2-methyl-2-propyl-1,3-propanediol dicarbamate, $C_{12}H_{24}N_2O_4$, M_r 260.33, *mp* 92–93 °C. Prepared by reaction of 2-methyl-2-propyl-1,3-propanediol with phosgene and ammonium hydroxide, then with isopropyl isocyanate [21].

Carisoprodol has an onset of action of ca. 30 min and a duration of 4–6 h. It is administered orally. Presumably, it acts by inhibiting interneuronal activity in the spinal cord and the brainstem reticular formation. Clinically effective doses are accompanied by drowsiness or dizziness; its mechanism may involve sedation. Its CNS depressant effects are additive with those of ethanol and other psychotropic agents. Carisoprodol has a low potential for drug dependence.

Trade Names. Caprodat (Ferrosan), Carisoma (Wallace), Flexartal (Clin-Comar-Byla), Mioril (Rossini), Rela (Schering), Relasom (Rafa), Soma (Wallace), Sanoma (Heilit).

Chlorphenesin carbamate [*886-74-8*], 3-(4-chlorophenoxy)-1,2-propanediol-1-carbamate, $C_{10}H_{12}ClNO_4$, M_r 245.68, *mp* 89–91 °C. Prepared by reaction of 3-(4-chlorophenoxy)-1,2-propanediol with phosgene and subsequent reaction with ammonium hydroxide [22].

Chlorphenesin carbamate is well absorbed after oral administration and has a duration of ca. 4 h. Its use is similar to carisoprodol.

Trade Names. Maolate (Upjohn), Rinlaxer (Upjohn, Taischo).

Chlorzoxazone [*95-25-0*], 5-chloro-2-hydroxy-benzoxazole, $C_7H_4ClNO_2$, M_r 169.58, *mp* 191–191.5 °C. Prepared by hydrolyzing 2-amino-5-chlorobenzoxazole in 1 mol/L HCl [23].

Chlorzoxazone has an onset of action of about 1 h and a duration of 3 – 4 h. It is administered orally. The metabolized drug is excreted in the urine as a glucuronide conjugate.

Trade Names. Biomioran (Bioindustria), Paraflex (McNeil), Solaxin (Eisai).

Cyclobenzaprine hydrochloride [*6202-23-9*], 5-(3-dimethylaminopropylidene)-dibenzo[*a,e*]cycloheptatriene hydrochloride, $C_{20}H_{22}ClN$, M_r 311.85, *mp* 216 – 218 °C. Prepared by Grignard addition of 5*H*-dibenzo[*a,d*]cycloheptanone with γ-dimethylaminopropyl chloride and subsequent elimination of water [24].

Cyclobenzaprine hydrochloride has an onset of action of about 1 h and a duration of 12 – 24 h. It is administered orally. It reduces muscular tension principally by inhibiting interneuronal activity in the brainstem reticular formation but also has activity at the spinal cord level [25]. It is chemically related to the tricyclic antidepressants and shares some of their pharmacological properties. Its CNS depressant effects are additive with those of ethanol and other psychotropic agents. It should not be administered in combination with monoamine oxidase inhibitors.

Trade Names. Flexeril (Merck, Sharp and Dohme), Yurelax (Organon).

Diazepam [*439-14-5*], 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one, $C_{16}H_{13}ClN_2O$, M_r 284.76, *mp* 125 – 126 °C. Prepared by numerous synthetic routes including reduction and methylation of 7-chloro-5-phenyl-3*H*-1,4-benzodiazepin-2(1*H*)-one 4-oxide [26].

Diazepam is administered orally for the relief of acute muscle spasms and for the treatment of chronic spasticity in patients with spinal cord lesions and cerebral palsey. It acts at supraspinal levels in the reticular formation to enhance presynaptic inhibition of the spinal reflex arc [27]. Secondarily, it acts at the spinal level to augment interneuronal inhibition of the reflex. See also → Psychopharmacological Agents, Chap. 4.1.; → Sedatives, Chap. 3.1.

Trade Names. Cercine (Takeda); Horizon (Yamanouchi); Lorinon (Hoechst); ValCaps, Valium, Valiquid (Roche), Valrelease.

Meprobamate [*57-53-4*], 2-methyl-2-propyl-1,3-propanediol dicarbamate, $C_9H_{18}N_2O_4$, M_r 218.25, *mp* 105 – 106 °C. Prepared by reaction of 2-methyl-2-propyl-1,3-propanediol with excess phosgene and ammonium hydroxide [28].

Meprobamate is rapidly absorbed after oral administration and has a duration of 3 – 4 h. Its primary clinical use is for daytime sedation in anxious patients, but it is occasionally administered orally as part of a regimen of bedrest and physical rehabilitation for painful musculoskeletal conditions. Mechanism of action and effects are similar to those of carisoprodol. See also → Psychopharmacological Agents, Chap. 4.2.

Trade Names. Aneural (Wyeth), Ayeramate (Ayerst), Equanil (Wyeth, Clin-Comar-Byla), Equatrate (Wyeth), Meprospan (Wallace), Meprotabs (Wallace), Miltown (Lederle, Wallace, Iribsa, Horner), Quaname (Wyeth), Quanil (Wyeth), Wyseals (Wyeth).

Metaxalone [*1665-48-1*], 5-(3,5-dimethylphenoxymethyl)-2-oxazolidinone, $C_{12}H_{15}NO_3$, M_r 221.25, *mp* 121.5 – 123 °C. Prepared by heating urea and 3-(3′,5′-dimethylphenoxy)-1,2-propanediol to 200 °C [29].

Metaxalone has an onset of action of ca. 1 h and a duration of 4 – 6 h. It is administered orally. Its clinical mechanism of action may involve sedative activity. Its CNS depressant effects are additive with those of ethanol and other psychotropic agents.

Trade Name. Skelaxin (Carnrick).

Methocarbamol [*532-03-6*], 3-(2-methoxyphenoxy)-1,2-propanediol 1-carbamate, $C_{11}H_{15}NO_5$, M_r 241.24, *mp* 92 – 94 °C. Prepared by reaction of 3-(2-methoxyphenoxy)-1,2-propanediol with phosgene and ammonium hydroxide [30].

Methocarbamol has an onset of action of 30 min and a duration of ca. 4 h. It is administered orally for treatment of painful musculoskeletal conditions. A parenteral formulation is available for intravenous or intramuscular administration. It is used to control muscular spasticity resulting from tetanus. Its clinical mechanism of action is unclear but may involve its sedative activity. Its CNS depressant effects are additive with those of ethanol and other psychotropic agents.

Trade Names. Lumirelax, Miolaxene (Merrel Dow, Lepetit), Robaxin (Robins), Traumacut (Brenner), Tresortil (Gea).

Orphenadrine [*83-98-7*], *N,N*-dimethyl-2-(2-methyl-α-phenyloxy)ethylamine, $C_{18}H_{23}NO$, M_r 269.37; citrate salt, $C_{24}H_{31}NO_8$, M_r 461.51. Prepared by reacting 2-methylbenzhydryl chloride with dimethylaminoethanol [31].

Orphenadrine citrate has a clinical duration of 4 – 6 h. It is administered orally or parenterally (intravenous or intramuscular). It reduces muscular tension principally by inhibiting interneuronal activity in the brainstem reticular formation, but its mechanism of action may be related to its analgesic activity. It has anticholinergic activity and should be used with caution in patients with cardiac disease.

Trade Names. (citrate salt) Banflex (Forest), Norflex (Rikker).

2.2. Treatment of Chronic Neurological Spasticity

The basic unit for the CNS integration of skeletal muscle tone is the reflex arc located in the spinal cord (→ Neuropharmacology, Chap. 3.2.1.). Specialized stretch receptors situated within muscle spindles (specialized muscle fibers) transmit information about muscle deformation to the spinal cord. The incoming signal activates spinal α-motor neurons innervating the stretched muscle to produce an increase in its tonus. Within the spinal cord, one (monosynaptic) or more synapses (polysynaptic) may be involved in the reflex path. Higher brain systems "fine tune" the stretch reflex by adjusting the sensitivity of the muscle spindle units through γ-motor neurons which adjust their "gain".

Multiple factors produce spasticity and it comes as no surprise that there is no satisfactory treatment. Drug therapy is limited in its efficacy by the interplay of the functional units of the nervous system: when one unit is favorably influenced by the drug, other units may be depressed or activated. Furthermore, nonselective reduction of muscle tone might not be in the

patient's best interest if abolition of spastic stiffness merely unmasks severe weakness. Reduction of muscle tone may only be indicated where the hyperexcitability interferes with function or hinders rehabilitation or nursing care. Sedation and other side effects which limit dosage regimens to suboptimal levels are another limitation of available therapy.

Baclofen [*1134-47-0*], γ-amino-β-(4-chlorophenyl)butyric acid, $C_{10}H_{12}ClNO_2$, M_r 213.67, *mp* 206 – 208 °C. Prepared by reduction of β- cyano-β-(4- chlorophenyl)propanoic acid [32].

Baclofen has a rapid onset of action and a duration of ca. 4 h. It is used for relief of flexor spasms and concomitant pain, clonus, and muscular rigidity resulting from multiple sclerosis [33]. Patients with complete spinal transections respond as well as those with partial spinal lesions. It depresses mono- and polysynaptic transmission in the spinal cord. It has affinity as an agonist at a subtype of the γ-aminobutyric acid receptor ($GABA_B$). Drowsiness, insomnia, dizziness, weakness, ataxia, and mental confusion are adverse side effects that limit its clinical usefulness. Sudden withdrawal has been associated with hallucinations. Baclofen is excreted unchanged by the kidneys.

Trade Names. Baclon (Medica), Gabalon (Daiichi), Lioresal (Ciba-Geigy), Myospan (Lagap).

Chlorpromazine hydrochloride [*69-09-0*], 2- chloro-10-(3-dimethylaminopropyl)phenothiazine hydrochloride, $C_{17}H_{20}Cl_2N_2S$, M_r 355.33, *mp* 194 – 196 °C. Prepared by reaction of 2- chlorophenothiazine with dimethylaminopropyl chloride [34].

Chlorpromazine hydrochloride has antispastic activity [35] when administered parenterally (intramuscular or intravenous) and is indicated for the relief of muscle spasms associated with tetanus. Its efficacy in spasticity is overshadowed by its sedative and other CNS side effects. It inhibits descending noradrenergic brain stem pathways which regulate fusimotor discharge [36].

Trade Names. Largactil (Rhône-Poulenc), Promacil (Knoll), Promexin (Meiji), Thorazine (SKF).

Tizanidine [*51322-75-9*], 5- chloro-4-(2-imidazolin-2-ylamino)-2,1,3-benzothiadiazole, $C_9H_8ClN_5S$, M_r 253.70, *mp* 221 – 223 °C. Prepared by reaction of 4-(2-imidazolin-2-ylamino)-2,1,3-benzothiadiazol-4- cyanoamine with ethylene diamine and subsequent chlorination [37].

Tizanidine is marketed in 23 countries worldwide for the treatment of spasticity. It is being evaluated in multiple sclerosis patients in the United States by Athena Neurosciences.

Trade Names. Sirdalud, Ternelin (Sandoz-Wander).

1. Introduction

1.1. Cosmetics and the Skin

Skin cosmetics are agents used in the care, cleansing, and decoration of human skin. The skin [1], with a surface area of ca. $2.0\,m^2$ in adults, constitutes the outer boundary of the human body with its environment. Skin is the largest human organ, and it fulfills various important functions. In addition to protecting against injury, environmental influences, dehydration, and desiccation, the skin serves to combat infection, regulate body temperature, and transmit sensory stimuli. The *epidermis* (outer skin) forms the actual protective covering. It consists of several layers: stratum basale, stratum spinosum, stratum granulosum, and stratum corneum (horny layer) as the outermost layer [2–7], which is an important permeability barrier.

Underlying the epidermis is a vascularized dermis that provides support and nutrition for the dividing cells in the epidermis (see Fig. 1). The dermis also contains nerves and appendages: sweat glands, hair follicles, and sebaceous glands. Nails are also considered as skin appendages. The subcutaneous fat is included as a third, deeper layer of the skin.

1.2. The Function of Skin Cosmetics

Skin cosmetics act on the epidermis or its outermost layers, but they are of great significance from the standpoint of function and appearance. Skin care measures should leave the skin's barrier function unaffected or even reinforced, and cleansing should inflict as little skin damage as possible. Decoration serves to visually enhance the skin color and structure. Skin cosmetics clearly differ from dermatological preparations, which induce effects below the epidermis in deeper layers on the skin, or even systemically (→ Dermatotherapeutic Agents). Dermatological preparations are in fact drugs used for treating skin diseases (dermatoses).

1.3. History

Preparations for the care, cleansing, and decoration of the skin have long been known [8]. For example, castor oil [*8001-79-4*] was used several thousand years ago in ancient Egypt as a protective balm. Among the Romans, Galen of Pergamon (A.D. 129 – 199) developed one of the first precursors of modern skin creams from a mixture of beeswax, olive oil, and rosewater (aqua rosae). Milestones in the preparation of ointment bases include the introduction of Vaseline [*8001-25-0*] by CHESEBOROUGH, as well as purified lanolin [*8027-32-5*] by LIEBREICH in the second half of the nineteenth century. The first stable water-in-oil skin cream was produced in 1911 (Nivea Creme).

2. Product Development

2.1. Choice of Raw Materials

A great many raw materials can be used in the formulation of cosmetics [9–11]. Choosing the

Figure 1. Subdivisions of the epidermis and dermis (× 256) (by courtesy of Little, Brown and Company, Boston, Mass.) a) Stratum corneum; b) Stratum granulosum; c) Stratum spinosum; d) Stratus basalis; e) Dermoepidermal junction; f) Papillary dermis; g) Reticular dermis

raw materials is an important first step, and it involves a balanced and thoughtful consideration of the following diverse factors:

Aesthetics
Availability
Color
Cost
Environmental compatibility
Functionality
Government regulations
Mutual compatibility with respect to other ingredients
Patent status
Processing characteristics
Skin and mucous membrane compatibility
Skin feel
Smell
Stability (chemical, physical, microbial)

Cosmetic raw materials are seldom pure substances; most are instead mixtures of a wide variety of individual components.

2.2. Tests for Stability and Effectiveness

Stability tests for skin cosmetics are of three types: physical, chemical, and microbial (see Section 12.2). Bacteria and fungi might conceivably contaminate an end product during either production or filling, but also later, during use, so microbiological evaluation must be conducted with extreme care [12], [13]. Of fundamental importance are the cosmetic properties of the product itself – that is, its aesthetic characteristics – as well as the state of the skin during and after product use. Evaluation is conducted within the framework of organoleptic and visual (i.e., sensory subjective) appraisal [14]. Objectively detectable changes in skin state are monitored by biophysical measurements. Many different methods are available [15], [16], including determination of the skin surface profile [17] and measurement of transepidermal water loss (TEWL) [18], [19].

3. Emulsions (→ Emulsions)

3.1. Introduction and Definition

Emulsions play a central role in cosmetics chemistry. Advances in cosmetic technology have opened the way to preparing otherwise impracticable combinations of constituents. Variation of rheological – tactile properties makes available a broad range of application forms (lotions, milks, creams, etc.) [20].

An emulsion is generally described as a thermodynamically unstable system consisting of at least two immiscible liquids, one of which is dispersed in fine droplet form in the other [21–23]. Unless an emulsion is stabilized, the two immiscible liquids tend to separate. Stabilization is achieved by incorporating emulsifiers into the interface, and through the use of additional polymers, solids, and liquid-crystalline phases [24]. The aggregation states of both the dispersed and continuous phases vary from highly liquid to semisolid [25]. Cosmetic emulsion systems thus cover the range from lotions (low viscosity) to semisolid preparations (ointments and creams) [26].

3.2. Composition and Classification

Cosmetic emulsions can be of three basic types: water-in-oil (W/O), oil-in-water (O/W), and bicoherent (e.g., multiple emulsions). Emulsions of the O/W and W/O type predominate in human skin care applications [27]. Different types of products (creams, lotions, milks, pastes, etc.) are preferred depending on the application site (e.g., body, face), and the intended use (care, cleansing, or decoration). Cosmetic preparations normally contain 5 – 50 % fat-like constituents (oils, fats, waxes), 1 – 10 % emulsifiers, and 50 – 90 % hydrophilic constituents (water and water-soluble ingredients) [28].

3.2.1. Emulsifiers

Emulsifier systems are constructed from appropriate lipophilic and hydrophilic molecular subunits. Proper selection of the components is critical to the stability of an emulsion. The choice is complicated by the fact that special characteristics of all the various substances in the system must be taken into account. The *hydrophilic – lipophilic balance* (HLB) is useful in selecting emulsifiers for the development of skin cosmetics [29–31] (→ Emulsions, Chap. 2.8., → Emulsions). Emulsifiers can be subdivided on the basis of their hydrophilic components into ionic (anionic, cationic, amphoteric) and nonionic materials. Common examples include:

1) Mixtures of fatty acids and their salts (e.g., stearic acid [*57-11-4*] and sodium stearate [*822-16-2*])
2) Ethoxylated fatty alcohols (e.g., polyoxyethylene (20) cetyl – stearyl ethers [*68439-49-6*])
3) Hydrogenated ethoxylated castor oils (e.g., polyoxyethylene (7) hydrogenated castor oil [*61788-85-0*])
4) Partial esters of fatty acids and modified fatty acids with glycerol, polyglycerol, and sorbitol (e.g., glyceryl monostearate [*123-94-4*], sorbitan monooleate [*1338-43-8*], and their ethoxylates)
5) Orthophosphoric acid esters (e.g., cetyl phosphate [*3539-43-3*])
6) Silicone surfactants (e.g., dimethicone copolyol [*64365-23-7*])

Detailed literature is available on the chemical structure, mode of action, and choice of emulsifiers for cosmetic products [32], [33].

3.2.2. Lipophilic Constituents

The lipophilic phase is normally a mixture of oils, fats, and waxes. It constitutes the "heart" of a cosmetic emulsion, since such product-defining properties as skin care and skin feel are strongly influenced by the composition of this phase. For example, it is responsible for "spreadability," (i.e., the tendency of an oil component to spread over the skin) and the "oily" feel of a cosmetic emulsion. Night creams are generally formulated to contain more fat and less spreading oil than day creams, which often contain easily spreading oils and more water. A wide range of oils, fats, and waxes is available commercially, corresponding to the central importance of these substances. These are divisible generally into the following groups:

1) Solid, semisolid, and liquid hydrocarbons (e.g., mineral oil [*8012-95-1*], petrolatum [*8009-03-8 (NF)*])
2) Natural oils and waxes (e.g., wheat-germ oil [*8006-95-9*], beeswax [*8012-89-3*])
3) Guerbet alcohols (e.g., 2-octyldodecanol [*5333-42-6*])
4) Partially hydrogenated and modified triglycerides (e.g., partially hydrogenated coconut oil, octanoic – decanoic acid triglyceride)
5) Fatty acid esters (e.g., cetyl palmitate [*540-10-3*])
6) Isostearic acid derivatives (e.g., isostearyl isostearate [*41669-30-1*])
7) Silicones (e.g., dimethicone [*9006-65-9*], [*63148-62-9*], [*9016-00-6*])

3.2.3. Hydrophilic Constituents

The aqueous phase of cosmetic emulsions generally contains desalinated water, which must be of high quality microbially. Other constituents normally include water-binding substances (humectants and moisturizers), such as the polyols, glycerol [*56-81-5*] and sorbitol [*50-70-4*], ethoxylated polyols, and hydrolyzed proteins. So-called natural moisturizing factor (NMF) – a mixture of amino acids, salts of pyrrolidonecarboxylic acid and lactic acid, urea, and other substances – is also used [34].

3.2.4. Additives

Additives important for product stabilization and the performance of cosmetic emulsions include:

1) Antioxidants to stabilize oxidation-sensitive oils, fats, and waxes
2) Preservatives (e.g., methylparaben [*99-76-3*], phenoxyethanol [*122-99-6*]) to protect against microbial infection of the product (consumer protection)
3) Chelate binders (e.g., ethylenediaminetetraacetic acid) to trap metal traces
4) Co-emulsifiers (e.g., cetyl alcohol [*36653-82-4*] and aluminum stearate [*7047-84-9*])
5) Acids and bases to regulate pH
6) Thickeners (e.g., one of the carbomers [*9007-16-3*], [*9003-01-4*], [*9007-17-4*], [*76050-42-5*]; cellulose derivatives)
7) Dyes, colored pigments, and white pigments, principally in decorative cosmetics
8) Light filters (sunscreens; see Chap. 11)
9) Perfume oils

3.2.5. Special Ingredients

Special ingredients, including so-called natural substances, are increasingly finding a place in face-care products [35]. The group of natural substances includes plant extracts (e.g., *Aloe vera* gel), natural biopolymers such as chitin [*1398-61-4*], collagen [*9007-34-5*], and hyaluronic acid [*9004-61-9*], and vegetable oils (e.g., evening primrose oil). Because of their sometimes problematic skin compatibility and tendency to sensitization, plant extracts must be tested thoroughly before being introduced into cosmetic emulsions.

The list of special ingredients also covers topically applied *vitamins*, particularly of provitamin B_5 (D-panthenol), and vitamin E and their derivatives, alone [36], or mixed with vitamin C and its derivatives.

More recently, special *carrier systems* (e.g., liposomes) have become important, especially in face care products. Liposomes are hollow spheres bounded by one (unilamellar) or several (multilamellar) lipid double membranes and containing one or more aqueous phases. Fat-soluble substances can be incorporated into the double membranes, and water-soluble substances can be enclosed within the spheres [37]. Phosphatidylcholine (PC) is thought to be the active agent in liposome sheath material from the standpoint of skincare. Liposomes can be regarded as combining the functions of both carriers and skin-related special ingredients. Microcapsules filled with active constituents have also been used as protection, sustained release, and transport vesicles [38].

3.3. PIT-Emulsions

3.3.1. General Introduction and Definition

Stabilization of an emulsion can be achieved by the addition of polymers, solids, or compounds that form liquid crystalline phases (see

Section 3.1). These ingredients increase the viscosity of the emulsion, thereby improving the stability of the final product.

A new low energy emulsification method called phase inversion temperature (PIT) method allows the formulation of finely dispersed low viscosity O/W emulsions without addition of the above-mentioned stabilizers. Emulsions can be thermally inverted by heating an oil-in-water (O/W) to a water-in-oil (W/O) emulsion (→ Emulsions, Chap. 1.). The inversion range is designated as phase inversion temperature [39].

3.3.2. Phase Behavior of Oil–Surfactant–Water Systems

The phase behavior of a ternary system consisting of oil, surfactant, and water can be represented in a triangular phase diagram. To study the influence of temperature on this ternary system a so-called "phase prism" is required, where the base specifies the composition and the vertical edge is the temperature axis [40], [41]. A section through the surfactant corner at a fixed water – oil ratio gives a temperature – surfactant concentration diagram that explains the different phases with respect to the temperature (so-called Kahlweit fish) [39].

3.3.3. Influence of Temperature on the Phase Behavior of an Emulsion

Heating a suitable mixture of an oil, an ethoxylated O/W surfactant (additionally a lipophilic cosurfactant) and water to 60 – 85 °C transfers an O/W emulsion to a W/O emulsion. During the heating process (O/W → W/O) and after the cooling process (W/O → O/W) the mixture shows a phase inversion. The resulting O/W emulsion (PIT emulsion) has a different droplet size distribution curve and smaller oil droplets than the O/W emulsion before the phase inversion process. PIT emulsions often have a bluish-white appearance.

Increasing the temperature of an O/W emulsion decreases the affinity of the hydrophilic ethylene oxide groups of the O/W surfactant to the water molecules. Heating of a PIT emulsion makes the hydrophilic O/W surfactant more hydrophobic, thereby increasing the solubility of the emulsifier in the oil phase and thus facilitating the formation of a W/O emulsion at higher temperatures.

3.3.4. Effects of Formulation Variables on Phase Inversion Temperature

The temperature at which phase inversion occurs depends on a number of variables [42] such as:

- Nature of the ethoxylated O/W surfactant (e.g., ethoxylated fatty alcohols, fatty acids, sorbitan esters, glycerol esters, or castor oils)
- Concentration of the ethoxylated O/W surfactant
- Nature and concentration of the W/O surfactant (glycerol esters, sorbitan esters, cetyl alcohols)
- Type and polarity of the oil phase

3.3.5. Nature of the Phase Inversion Area

The colloidal structure of the emulsion in the phase inversion range depends on the concentration of the surfactant (or the concentration of the water phase) in the composition. Several phases at 60 – 85 °C have been detected such as W/O microemulsions, lamellar liquid crystals, or bicontinuous microemulsions [43], [44]. In the phase inversion area the hydrophilic and hydrophobic properties of the O/W surfactant are balanced and a minimum interfacial tension between the oil phase and the water phase can be observed.

3.3.6. Physicochemical Characterization of the Phase Inversion Temperature

The phase inversion in emulsions is often accompanied by sharp changes in the physical properties, since different colloidal phases are involved in the process.

3.3.6.1. Electrical Conductivity Measurement

Cooling down a W/O emulsion to an O/W emulsion via a PIT process can be followed

by measuring the conductivity, since the external oil phase of the hot W/O emulsion does not contribute to the conductivity [45]. The increase in conductivity during cooling in a conductivity – temperature diagram shows the beginning of the phase inversion process of the composition.

3.3.6.2. Interfacial Tension Measurement

The interfacial tension is dependent on the temperature, measurement with a spinning drop tensiometer usually yield very low tension values (10^{-3} mN/m) in the PIT range [46]. At a constant concentration of the oil phase, the minimum level of the interfacial tension depends on the relative proportion of the O/W to W/O surfactant, the total amount of both surfactants, and the ethoxylation degree of the O/W surfactant.

3.3.7. Emulsification Production Process and Emulsification Routes

The knowledge of the phase behavior of an emulsion composed of an oil, an O/W surfactant (additionally a cosurfactant), and water allows the formulator to develop different strategies to prepare a PIT emulsion.

Hot – Cold Process. A preconcentrate is formulated where only part of the water phase is heated with the other components to the PIT range or above the PIT [43], [47]. Dilution of the hot mixture with cold water gives the final composition. This route is advantageous when temperature sensitive actives or perfumes are contained in the final product since in this case the cooling process of the hot W/O emulsion to the final PIT emulsion is faster than in the hot – hot process.

Hot – Hot Process. In the one-step process, all components are mixed together and heated above the phase inversion temperature [43], [47]. Cooling the composition to room temperature gives the finely dispersed bluish white product.

The droplet size is usually in the range of 100 to 250 nm in both processes. Preparing an emulsion suitable for phase inversion without heating the composition above the PIT usually gives a coarse emulsion with a droplet size distribution around 1000 nm [43].

3.3.8. CAPICO Method (Calculation of Phase Inversion in Concentrates)

Hydrocarbons as an oil phase in PIT emulsions show a linear dependence of the phase inversion temperature on the alkyl chain length (alkane carbon number, ACN) [39], [48], [49].

The interaction of the emollient and the O/W surfactant can be described by the hydrophilicity factor (HF) of a surfactant. Determination of the HF factor of an O/W surfactant is possible by measuring the temperature of phase inversion of oils with different alkyl chain lengths (different ACN values). The intersection of the graph with the ordinate in a PIT-ACN diagram gives the PIT_o value [39].

$$\mathrm{PIT} = \mathrm{PIT}_0 + (\mathrm{SF} \times \mathrm{ACN})$$

where SF is the sensivity factor (slope of the graph).

The advantage of the CAPICO method lies in the fact that it is possible to determine the expected temperature of phase inversion or the optimal surfactant : cosurfactant ratio for a desired PIT before preparing the product since many of the ACN, SF, and PIT_o values are published [39].

3.3.9. Applications [50]

Deodorants or antiperspirant pump sprays are usually water – alcohol solutions with a deodorant or antiperspirant active. The alcohol content is not suitable for consumers with sensitive skin, especially if the axillae are shaved.

Low viscous and sprayable deodorant PIT emulsions for the European market have been developed by several companies in the last few years. These products give a nice skin feeling and are free of alcohol.

Suncare Products. The PIT technology has been used to formulate sprayable suncare products. The homogenous distribution of the emulsion droplets facilitates a good distribution of the UV filters on the body. Furthermore, the consumer's hands do not come into direct contact with the product, making application more easy.

3.4. Stability and Product Safety

Emulsions are thermodynamically unstable structures. Depending on relevant legal statutes market-ready cosmetic emulsions are expected to be stable for several years at various temperatures; comprehensive testing is necessary to satisfy these requirements (see Chap. 12). Furthermore, cosmetic emulsions may not induce toxic responses when applied in accordance with instructions. Therefore, new developments have to be thoroughly tested in terms of their compatibility and dermatology tests, before the product is introduced to the market (see Chap. 13).

3.5. Cosmetic Properties

In addition to the aforementioned properties, public acceptance is an essential criterion for a cosmetic emulsion, particularly with respect to products for facial use. Consumer acceptance is generally based on two factors:

1) Objective effectiveness of the product. This is established by skin evaluations based on biophysical criteria, e.g., degree of moisture and roughness of skin (see Section 2.2).
2) Subjective effectiveness of the product (cosmetic elegance). The cosmetic elegance and tactile characteristics of a cosmetic emulsion can be determined by suitable test panels [51], [52].

3.6. Production

Generally speaking, the production of cosmetic emulsions involves three steps:

1) Preparation of the various phases (fat, water, thickeners, etc.) and then combining them in an appropriate sequence
2) Emulsification (i.e., comminution of the components by stirring)
3) Homogenization, achieved by further disintegration of the fat and water droplets in a homogenizer

A suitable formulation is first developed on a 1 – 2 kg scale (bench scale) using raw materials of the types described above. The procedure is then adapted to a 10 – 100 kg (pilot-plant) scale for further study prior to moving to full production scale (500 kg to several tons). Descriptions of appropriate scaleup and processing procedures can be found in [53].

4. Gels

Gels are enjoying increasing popularity. They correspond well to the prevailing "ethos" of modern cosmetology in that they combine functionality and elegance with an attractive image. The variety of available gel types permits a gel formulation to be adapted to suit nearly every cosmetic product group.

Gels are systems consisting of at least two components, generally a solid dispersed colloidally in a liquid dispersing agent [52] (→ Colloids). The dispersed particles form spatial networks in the dispersing agent that are stabilized by means of van der Waals forces, whereby the dispersing agent acts as a solvate sheath [20]. Gels can be of various types depending on their chemical composition. *Hydrogels* contain water as the dispersing agent, whereas in *lipogels* this role is played by oils.

4.1. Lipogels

Lipogels are preferred whenever skin-protecting effects are desired. Lipogels adhere to skin for a long time, and they provide a water-repelling effect. For this reason they are particularly suitable for hand care products and in sunscreen preparations for water sport enthusiasts [20], [54].

Depending on the intended use, lipogels are prepared from semisolid fats and waxes mixed with vegetable oils, longer- chain paraffins together with volatile silicones (e.g., cyclomethicone), or colloidal swelling agents (Aerosil, bentonite) in conjunction with mineral or vegetable oils. The firmness of a gel is determined by the content of microcrystalline components. Transparent gels result when the oil component has roughly the same refractive index as the incorporated solid (e.g., mixtures of esters of higher fatty acids or paraffin oil with Aerosil).

4.2. Hydrogels

Hydrogels can in turn be subdivided into polymer gels and hydrodispersion gels.

4.2.1. Polymer Gels

Polymer gels are widely used in skin- care cosmetics, particularly for fat- and emulsifier-free formulations. They readily release moisture, at the same time producing a marked cooling effect on the skin due to latent heat of vaporization. Several types of polymers have been employed:

Inorganic gel-forming agents, principally the colloidal silicic acid known as Aerosil and the swelling clay bentonite [55–58].

Natural organic gel-forming agents, including disaccharides and polysaccharides, as well as proteins of vegetable and animal origin (e.g., agar-agar or gelatin).

Semisynthetic organic gel-forming agents, such as biosynthetic rubbers (xanthanes, dextrans), starch fractions and starch derivatives (pectins, dextrins), and cellulose derivatives (cellulose ethers of widely varying types) [55], [59].

Synthetic organic gel-forming agents, the most important of which is polyacrylic acid (Carbopol), which forms a gel only after neutralization with an inorganic or organic base [55], [60].

A particular gel-forming agent is selected on the basis of its structure-forming properties, its compatibility with other raw materials and active constituents, and its behavior and function with respect to skin. It is important to note in this context that cellulose ether gels dry on the surface of the skin to form thin films, whereas polyacrylate gels are absorbed [61], [62].

Surface-active polyacrylates (Pemulen types) are increasingly being used to produce so- called quick-breaking emulsions. These are lipid- containing, creamlike gels that are highly sensitive to electrolytes; even the electrolyte content of normal skin is sufficient to destabilize them immediately (i.e., to break up the emulsion). The result is a full-bodied gel that is, nevertheless, rapidly absorbed. Detailed and comprehensive information is available from various distributors on the handling of gel-forming agents (suitable concentrations, dissolution behavior, nature of the dispersion, etc.). The testing process for gels from the development stage to marketing is similar to that of other cosmetic products (see Chaps. 12 and 13). Hydrogels are susceptible to microbial infection, and they are extremely light sensitive, especially polyacrylate gels, which means that special precautions must be taken during formulation and packaging development.

4.2.2. Hydrodispersion Gels

Hydrodispersion gels contain an additional oil phase. These emulsifier-free systems with oils and actives are sometimes used for sun-care products that are free of adverse reactions for consumers during a sun bath.

4.3. Lecithin Organogels

Lecithin organogels are made up of a three-dimensional network of entangled flexible tubular reverse micelles [77]. Lecithin organogels are prepared by addition of small amounts of water into an oil – lecithin mixture. At first spherical reverse micelles are formed. By further addition of water the inverted micelles undergo a one-dimensional growth to tubular aggregates ("wormlike micelles", polymer-like micelles) [78]. The result is the formation of a gel of a low-viscous, oily composition. The water channels and the oil phase of such systems are used to encapsulate different actives [79].

Lecithin organogels are also referred to as microemulsion gels (see Section 4.6). However, this classification is not justified (see page 11).

4.4. Gel-Emulsions

Product with a high amount of the internal phase are also known as high internal phase ratio emulsions (HIPRE) [80]. Due to their high water content, viscosity, and translucence they are also referred to as gel-emulsions. The viscosity is achieved by a large internal phase volume that exceeds 0.74, which corresponds to that of the closed-packed-sphere packing [81]. These gel-emulsions are formed in ternary mixtures of water, nonionic surfactant, and oil. They can contain up to 99.5 % of water with a very low content of surfactant (0.1 %) [82]. Some systems are

described as water-in-(water-in-oil microemulsions) emulsions. The structure of these emulsions is similar to that of a foam in which the gas is substituted by water and the continuous phase is a microemulsion of the water-in-oil type.

4.5. Surfactant Gels/Detergent Gels

The incorperation of a larger amount of a surfactant (> 10 %) into water or an oil phase transfers the low viscous micellar or reverse micellar solution into other colloidal phases. The phases that can occur upon increasing the surfactant concentration are classified as hexagonal, lamellar, inverted hexagonal, or reversed micelles [83], [84]. This phase sequences is not observed with every surfactant. Sometimes only a few phases occur upon increasing the surfactant concentration. A cubic phase can additionally be present in a system between micellar – hexagonal, hexagonal – lamellar, lamellar – inverted hexagonal or inverted hexagonal, and inverted micellar phases. The viscosity of these systems is often quite different from a free flooding gel to a stiff gel. Some of the former show the ringing gel effect when apping a glas vial containing such a surfactant – water mixture. Surfactant gels were classified as microemulsion gels in the past.

4.6. Microemulsion Gels

Definition of Microemulsions. A microemulsion is a thermodynamic stable, clear dispersion of two immiscible liquids (water and oil) containing an appropriate amount of surfactants and cosurfactants [85]. The viscosity of an oil-in-water and a water-in-oil microemulsion is usually very low. Both systems contain globular structures (oil nanodroplets or water nanodroplets). Bicontinuous microemulsions with an equal amount of water and oil are often more viscous (gel-like appearance) [86]. In this case the structure is not globular, the phase consists of relatively large interconnected and highly disordered oil and water domains, separated by the film of the surfactant monolayer. The analysis of the phase behavior of various surfactant – oil – water compositions leads to a better understanding of the colloidal phases of such compositions. Some of the systems described as microemulsions or microemulsion gels in the past are nowadays classified differently, e.g., lecithin organogels (Section 4.3) or surfactant gels (Section 4.5).

W/O-microemulsion gels are obtained by mixing water. AOT (an anionic surfactant) and an oil phase with gelatin as a polymer [87]. The gelatin is dissolved in water nanodroplets (nanogel droplets). At a specific polymer concentration the gelation of such a system occurs by a crosslinking process of the nanodroplets via gelatin helix – helix interactions in the oil phase. Another approach to these systems are hydrophilically modifies oil-soluble polymers. The formation of a polymer-mediated three-dimensional network of nanodroplets explain the gel character of such formulations.

O/W-microemulsion gels are obtained by adding a hydrophobically modified water-soluble polymer (cetylhydroxyethyl cellulose, PEG-150 distearate) to a low viscous microemulsion. The concentration of surfactants is very low (< 10 %).

4.7. Water-in-Silicon Oil Gels

By matching the refractive index of the water and oil phase it is possible to achieve transparent products [90], [91]. They are not classified as W/O microemulsion gels because they are not thermodynamically stable. In the US, deodorant gels are often based on this technology.

Silicone formulation aids (Dow Corrning 3225 C) are mixtures of cyclomethicone and dimethicone copolyols helping to solubilize the antiperspirant active. Low surface tension of cyclomethicones faciliates good spreading of a product on the skin and reduces the tackiness of antiperspirant active.

5. Oils

Cosmetic oils have been developed to satisfy a variety of needs, including:

Skin cleansing	makeup removers, baby oils
Skin care	moisturizers
Skin protection	UV protection (through the use of oil-soluble UV filters), protection against frostbite, protection against excessive dehydration from swimming
Special purposes	massage oils, bath additives, hair- care oils

Cosmetic oils are usually single-phase systems that are liquid at ambient temperature [65], [66].

5.1. Ingredients

The basic components of cosmetic oils are vegetable oils, synthetic fatty acid esters, hydrocarbons, silicone oils, mineral oil, and triglycerides of various chain lengths. Depending on the intended use, active ingredients may be incorporated, such as plant extracts, oil-soluble vitamins, and UV filters. Where necessary, antioxidants or UV filters are added to impart stability. In contrast to typical single-phase oils, hydrophilic oils contain a specific amount of an oil-in-water emulsifier to induce formation of an emulsion on contact with water. Typical emulsifiers include fatty alcohol polyglycol ethers, sorbitol fatty acid polyglycol ethers, and phosphoric acid esters.

5.2. Production

The production of cosmetic oils is quite simple when the components are anhydrous. Turbidity may develop with water- containing components, and for this reason, such ingredients (especially mineral oil) must be dehydrated by stirring under vacuum at 75 – 80 °C. After dehydration, the ingredients are combined with constant stirring. Temperature-sensitive ingredients must be added at $\leq$ 60 – 65 °C.

6. Lipsticks

6.1. Lip Protection

The skin of the lips [67] has a tendency to dry and develop small cracks, especially when exposed to cold, dry air [68], which then makes this particular skin extremely sensitive to other external influences. Lips must therefore be accorded special care and protection.

Apart from this consideration, the purely decorative aspect of lipstick or of lips of course plays a significant role [69]. Because of their convenience and functionality lipsticks occupy the dominant market position in the care and decoration of the lips.

The ideal lipstick should be easy to apply, and it should have a neutral taste. Light pressure on the stick should produce a film of fat that adheres well to the lips, leaving them smooth and supple, but the film should not be greasy, sticky, or subject to smudging. In the case of decorative lipsticks, the goal is an indelible coloring of the lips coupled with firm adherence of the coloring matter. Unfortunately, the requirements for stability conflict with the ideal application properties. A lipstick must also be mechanically stable and temperature resistant, and it must not "sweat" (i.e., there should be no visible separation of small oil droplets) [70]. With decorative lipsticks it is necessary to pay special attention to the stability of the coloring agents.

6.2. Composition

Lipsticks are normally anhydrous mixtures of fat, oil, and wax [71–73]. Water- containing formulations are an exception [74]. Uncolored lipstick base compositions can be subdivided roughly into the following groups of raw materials:

1) Liquid oils (e.g., mineral oil, castor oil)
2) Semisolid constituents (e.g., petrolatum, lanolin)
3) Solid constituents (e.g., ceresin, beeswax)
4) High-melting waxes [e.g., carnauba wax (from *Copernicia prunifera*)]

Microcrystalline paraffin waxes (e.g., ozokerite and ceresin), because of their oil-binding properties and relatively low thermoplasticity, are important constituents of high-quality lipstick bases (→ Waxes). In combination with high-melting waxes they constitute the framework of traditional lipsticks. Carnauba wax, one of the hardest and highest-melting (*mp* 83 – 86 °C) natural waxes, is particularly important in this respect, since it substantially increases the strength of a lipstick.

6.3. Testing

Lipsticks are evaluated on the basis of utility, appearance, color, ability to produce uniform col-

oration, adhesion, fragrance, and taste. Other criteria include the results of storage tests at various temperatures, heat stability, weight loss, fracture stability, and cohesion of the lipstick composition in its holder.

6.4. Production

Once an elegant and stable lipstick formulation has been devised it is crucial that a simple and unproblematic production process be developed. Normally the fat component is melted and cast directly. Important parameters include, among others, the casting and cooling temperatures [75].

7. Shower and Bath Preparations

(→ Soaps)

Cleansing of the skin is certainly one of the oldest human customs. Along with hygiene, religious and cultural factors have often played an important role in cleansing activities. Consumers expect more from modern bath and shower products than mere cleansing, including refreshment, stress relief, stimulation, and grooming.

7.1. Composition

7.1.1. Surfactants

The most important constituents of cleansing products are surfactants, with the task of reducing the surface tension of water so that thorough wetting can occur and dirt can be solubilized and removed from the skin (→ Surfactants; → Laundry Detergents, Chap. 3.1.). A choice of surfactants is made on the basis of consumer expectations; that is, the product must not only cleanse effectively, it must also foam well even when charged with dirt, sebum, and grease. These requirements are met largely by anionic and amphoteric surfactants [76]. Nonionic surfactants have so far been used to only a minor extent in special products because of their unsatisfactory foaming power, although increasing attention has recently been paid to this group of substances.

Anionic Surfactants. The most important anionic surfactants include alkyl sulfates and alkyl ether sulfates; alkyl and olefin sulfonates, as well as sulfosuccinates, and sulfoacetates; alkylethercarboxylic acids; and fatty acid – protein condensates.

Alkyl sulfates develop a good foam, are resistant to hard water, and display powerful cleansing and degreasing action. Unfortunately, they also exhibit a high protein-binding capacity and poor mucous membrane compatibility, and for these reasons, they are of limited suitability for body- cleansing purposes, and must be mixed with other, milder surfactants.

Alkylether sulfates are widely used in Europe in the production of shower and bath preparations. In particular, compounds with a $C_{12}-C_{14}$ alkyl chain and an average degree of ethoxylation of 2 – 3 mol of ethylene oxide are extremely water soluble, foam strongly even in hard water, and can be thickened with electrolytes (e.g., sodium chloride).

Sulfosuccinate and sulfoacetate esters produce a creamy foam and have outstanding skin and mucous membrane compatibility. Their disadvantage, however, is that they tend to hydrolyze. They are therefore used preferentially in neutral to weakly acidic products.

Protein – fatty acid condensates and alkylethercarboxylic acids are, because of their excellent skin compatibility, used particularly for especially mild preparations.

Amphoteric surfactants [77] can be divided into two main categories: the alkylbetaines and the alkylamphoglycinates and amphopropionates. Betaines, such as cocamidopropylbetaine [*61789-40-0*]

produce creamier and more stable foams than anionic surfactants. When combined with anionic surfactants they also have a thickening effect. Alkylamphoglycinates and alkylamphopropionates show even better compatibility, but their foam characteristics are poorer.

Nonionic surfactants usually foam very little, in contrast to the types mentioned above. Examples include the fatty alcohol ethoxylates or fatty acid polyglycerides, which are among the mildest surfactants that exhibit a detectable level of skin substantivity. Alkylpolyglucosides have also been known for a long time, but only recently have they been used to a significant extent. They display good foam and cleansing properties, as well as good skin compatibility.

7.1.2. Auxiliaries

The production of cosmetically attractive, functional, and hygienically effective shower and bath preparations requires the addition of such auxiliaries as thickening agents, foam stabilizers, fat-restoring agents, turbidity agents, complexing agents, and preservatives.

Thickening agents serve to adjust the viscosity, at the some time contributing to the stabilization of pearl-luster or turbidity agents. Various substances are available for this purpose, depending on the formulation and the desired effect (e.g., fatty acid alkanolamides, cocamide MEA, see structure below). Electrolytes, and (to some extent) amphoteric surfactants cause micelles to become larger, thereby increasing the viscosity.

R = alkyl, $C_{12}-C_{14}$

Other substances, such as poly(ethylene glycol) fatty acid esters or hydroxyalkyl cellulose and polyacrylate polymers, create three-dimensional structure, which tends to thicken the aqueous phase.

Foam stabilizers (→ Foams and Foam Control) increase the "creaminess" and stability of foams. The main examples are fatty acid monoalkanolamides and dialkanolamides, polymers, protein – fatty acid condensates, and proteins, all of which have been mentioned previously.

Fat-restoring substances act either by minimizing fat removal from the skin or by restoring lipids to it. Monofatty acid esters of glycerol and diglycerol are particularly suitable for this purpose because of their amphiphilic character and their structural relationship to the natural cutaneous lipids.

Pearl-luster and turbidity agents are often added to shower and bath preparations to enhance properties such as "creaminess" and "richness" consistent with consumer demand. Higher fatty alcohols, insoluble fatty acid alkanolamides, ethylene glycol distearates, monoesters of polyhydric alcohols, and polystyrene emulsions are used for this purpose.

Complexing and sequestering agents form chelates with a wide variety of cations, (e.g., calcium, magnesium, and iron or other heavy metals), thereby suppressing possible decomposition reactions in the product (e.g., Haber – Weiss reactions [78]).

Preservatives are intended to prevent microbial spoilage. The substances chosen and the levels at which they are introduced are largely a function of product composition. The more hydrophobic a preservative, the greater is the danger that it will be trapped in surfactant micelles and thus no longer be effective against microorganisms. For this reason, comprehensive microbiological tests are necessary in each case.

7.2. Product Forms and Types

Cleansing products from the cosmetics industry can be subdivided into liquid and solid preparations. Liquid cleansing preparations are further subdivided into products for the shower, foam baths, cream baths, and oil baths. The latter consist mainly of lipids. Foam and shower products are almost exclusively surfactant preparations. Cream baths occupy an intermediate position. New products in the form of concentrates reflect growing ecological concerns, since their compactness produces savings in packaging materials and transportation. In principle, these new products are formulated in the same way as other liquid preparations, although the raw materials and production methods differ from those of conventional forms. Solid cleansing products include, in addition to soaps (→ Soaps), bath salts,

powders, and tablets. The principal constituents in this case are sodium hydrogencarbonate and sodium metaphosphate. Talcum, silicates, and starch are added as binders. Gelatins and pectins serve as dusting agents.

7.3. Production

Shower and bath preparations are mass-produced products, so the production methods must permit homogeneous mixtures to be prepared rapidly. If all the raw materials are pumpable at room temperature and large amounts of finished product are required, continuous production is employed, with outputs of 5 t/h. All the components are introduced in-line into static mixers via reciprocating pumps. Consistent product quality is ensured by means of measuring and regulating circuits. A batch process is preferred for processes involving more time- consuming mixing, as in the incorporation of solids or the melting of partial phases. In addition to effective, thorough mixing, care is required to ensure that a foam-free product results. Simple, propeller-type stirring equipment is therefore unsuitable. Guided jet mixing turbines have proved effective for this purpose.

8. Deodorants and Antiperspirants

Body odors served originally as a vehicle for facilitating social communication. Thus many animals secrete from special scent glands substances known as pheromones that strongly influence sexual and territorial behavior. Evolution has resulted in this form of communication becoming much less important for humans as evidenced by a severely atrophied human sense of smell. A marked exception to this rule is axillary odor. This very intense odor is now regarded as extremely unpleasant, and it is unacceptable in modern society. One approach to preventing the spread of body odor is the use of deodorants.

The Origin of Body Odor. Body odor is produced by the action of bacteria on apocrine sweat. Living conditions are ideal for such microorganisms in the moist and warm environments of armpits and similar parts of the body [79]. Various gram-positive bacteria are implicated in the decomposition of sweat, which is itself odorless. Two main types of body odor can be assigned to specific types of bacteria. Kligman [80] ascribes the weaker "acid" odor to micrococci, and the "sharp" pungent odor to lipophilic diphtheroids.

8.1. Composition

As the name implies, a *deodorant* is intended to make body odor imperceptible, and various approaches can be adopted to achieve this end.

Antiperspirants reduce the secretion of sweat by partially blocking the outlets of the eccrine sweat glands [80]. This effect is achieved mainly by the use of astringents, such as aluminum salts. The basic aluminum chlorides, such as aluminum chlorohydrate (Chlorohydrol), have proved especially suitable. Mixtures of aluminum and zirconium salts are also used, especially in the United States. These are more effective than Chlorohydrol, but are prohibited for use in aerosols because of their inhalation toxicity.

Antibacterial agents are also important aids in effectively combating body odor. Specific antimicrobial agents are chosen for their selective action against odor-producing bacteria. Examples include *triclosan* (2,4,4′-trichloro-2′-hydroxydiphenylether) [*3380-34-5*], *chlorhexedine* [1,6-di(4- chlorophenylbiguanido)hexane] [*3697-42-5*], and *TCC* (3,4,4′-trichlorocarbanilide) [*101-20-2*].

Doubts were raised in Europe in 1987 concerning the safety of triclosan because of dioxin contamination, so attention has increasingly been redirected to older, well-known odoriferous substances with antibacterial action: essential oils, typically including such constituents as clove oil, mint oil, or thyme oil. Because of their strong intrinsic smell these substances can be used only to a limited extent. An interesting active substance from plants is the terpene alcohol *farnesol* (3,7,11-trimethyl-2,6,10-dodecatrien-1-ol) [*4602-84-0*], which combines good antimicrobial properties with a weak intrinsic smell. *Nisin* [*1414-45-5*] is a peptide with a very selective effect on the lipophilic diphtheroids [81].

Odor absorbers are compounds with the ability to bind odor-forming components. They act by lowering the partial vapor pressure of the bound substance, limiting its progagation rate. Suitable active ingredients include complex zinc salts of ricinoleic acid (12-hydroxy-9,10-octadecenoic acid) [*141-22-0*] or mixtures of special fragrances with a neutral smell.

Odor maskers have existed since the invention of perfumes. They are used to hide body odor, and represent the "classic" method of dealing with it. Even today the presence of perfume contributes substantially to the effectiveness of a deodorant.

8.2. Application Forms

Despite the controversy surrounding propellants, *aerosols* still account for a large part of the deodorant market. Aerosols are alcoholic solutions of active ingredients that have been introduced into their containers under pressure, generally in conjunction with a liquefied gas that serves as a propellant, all in such a way as to form a homogeneous solution. When an aerosol is sprayed the propellant gas vaporizes suddenly and violently, breaking the alcohol solution into very fine droplets (aerosol formation, → Hair Preparations). Hydrocarbons such as propane, butane, and isobutane have largely replaced the chlorofluorocarbons (CFCs) formerly used as propellants. In addition to the alcoholic sprays, there also exist dry deodorant sprays, which are generally antiperspirant suspensions.

Pump atomizers, whose contents consist essentially of aqueous alcoholic solutions, are becoming increasingly popular. The solubility of perfume oils and other hydrophobic substances decreases with increasing water content, so emulsifiers and solubilizers must generally be added to these formulations.

Roll-on dispensers are designed to hold liquid deodorants formulated to have a specific viscosity, thereby ensuring that the contents will be transferred satisfactorily to the skin by the action of a roller ball. Both liquid gels and oil-in-water emulsions have been developed to meet this requirement.

Deodorant sticks must satisfy two conditions: on the one hand they must be hard and dimensionally stable, but at the same time the contents must be transferable to the skin with a light, gentle pressure. Transparent sticks based on soap – glycol gels have such properties. In the presence of long-chain fatty acid sodium salts (soaps), the lower glycols form clear gels with the capacity to absorb both alcohol and water. The *powder stick* represents another type of deodorant. In addition to talcum and aluminum salts, its basic formulation includes fats, waxes, and volatile silicone oils, the latter usually in substantial proportion.

8.3. Testing

To check the effectiveness of potential deodorant active constituents or new formulations, microbiological in vitro methods are invoked first [82]. The effectiveness of an odor absorber can be determined by headspace analyses. After these preliminary tests, consumer-oriented sniff tests are generally conducted. Here each tester is required to use two different products under specified conditions, in most cases for two weeks. The intensity of residual body odor is then determined at prescribed intervals [83].

8.4. Production

The production of deodorants is relatively simple, since all the necessary components can easily be mixed. However, production must always be carried out under explosion-proof conditions because of the alcohol content. Aerosols require special technical equipment for filling and sealing the containers and charging them with propellant.

9. Body Powders

A body powder is an aggregation of solid particles intended as a medicinal or cosmetic preparation for external application to the skin. One function of the particles is to offer mechanical protection, but they also confer a drying and cooling effect and serve as a base for active constituents. The cooling effect is achieved by added stearates or starch. Colloidal silica, precipitated silicic acid, and magnesium carbonate serve to

enhance the drying effect. The surface slip of a powder is increased by the addition of talcum, and adhesion is improved by introducing lubricating components such as petrolatum, paraffin oils, wool wax, or stearates. The properties of powder bases have been described in detail in [84]. Their production is discussed in Section 10.3.

Most modern body powders provide drying or deodorant action. Talcum is the usual base, supplemented with a bacteriostatic agent. Products of this type are available for use on the feet, hands, and axillary regions of the body. Years ago, vulnerary or healing powders were also common cosmetic items, but today these are considered to fall in the medicinal sector, one notable exception being baby powders.

10. Decorative Body Agents, Cosmetics, and Makeup

The desire to appear beautiful and attractive is deeply rooted in human nature, and has affected behavior for thousands of years, even though the means for achieving beauty and the very concept itself have changed constantly over the course of time. More than a thousand years before Christ the Egyptians were already tinting their skin, applying rouge, and highlighting their eyebrows. Present-day concepts of beauty are based on a desire for the face to appear as natural and well groomed as possible. Shades considered appropriate for this purpose vary greatly depending upon current fashion and the type of person involved.

The term decorative cosmetics designates a large variety of different product groups, for example lipsticks, emulsions, gel based formulations and powders. The main difference to skin care products is their content of color pigments (between 3 and 50 %), depending on the formula type and the desired optical effect.

10.1. Types of Decorative Cosmetics

Foundations. The aim of this product type is to freshen and highlight the skin tone and smooth out slight irregularities. In some countries these facial cosmetics are also termed “makeup”.

Foundations are mainly O/W emulsion-based products (see Section 3.2) containing about 5 – 10 % color pigments, usually iron oxides. The consistency of these products can vary between very liquid and creamy.

A *compact foundation* is much more solid and typically poured in a godet after preparation. The formulation of compact foundations is based on a wax-oil base, that contains powdery filling agents such as talcum and 10 – 15 % color pigments (iron oxides and pearlescent pigments). These foundations have mostly a higher coverage than emulsion-based products and have to be spread with a sponge on the skin.

Decorative Eye Cosmetics. They are intended to impart expression to the eyes. The most common eye products are eye shadow powders, mascaras, eyeliners, and pencil products for eyelids and eyebrows.

Eyeshadow powder is a combination of pressed powdery raw materials such as talc, zinc oxide, inorganic and pearlescent pigments, and about 5 % of easily spreadable oils. It is pressed in metal godets and applied with a little sponge or brush.

Mascaras are creamy O/W emulsions containing mostly black iron oxides (up to 15 %). They are applied with a special brush directly on the eyelashes to color them and make them look more expressive.

Liquid eyeliners are applied with a very tiny brush directly on the eyelid above the lashes. Their basic formula is similar to that of mascara, except that the viscosity is much lower to facilitate application.

Examples for *pencil products* are: Eyeliners; kajal, which can be directly applied in the inner eyelid area; or eyebrow pencils which are applied on the eyebrows. The inner part of these pencils is a poured or extruded lead, based on waxes, oils, and color pigments; the outer part consists of wood or plastic.

Lipsticks. The most common and fashion related decorative product is the lipstick. A large variety of colors are available to impart more emphasis and expression to a women’s face.

A modern lipstick is composed of suitable mixture of high and low melting waxes; inorganic, organic, and pearlescent pigments; and a

composition of oils. Castor oil is the most commonly used oil because of its glossy effect on the lips and easy dispersion of the color pigments.

Lipsticks are discussed in detail in Chapter 6.

Nail Varnish/Nail Polish. To highlight the fingernails and toenails, these quick-drying lacquer formulations are available in a very large variety of shades. Nail polishes are anhydrous compositions of film formers, plasticizers, and a mixture of suitable solvents. As color components inorganic and organic pigments are used as well as pearlescent pigments to impart the lacquer a metallic shine.

Nitrocellulose is traditionally used as the base for nail polish because of its ideal film forming properties. As plasticizer camphor and dibutyl phthalate are frequently present. Polyacrylates or polymethacrylates are employed to add luster. Solvents are used to control flow, viscosity, evaporation rate, and drying time of the polish. The most widely used solvents are butyl acetate and ethyl acetate.

10.2. Colorants

The following colorants are the ones most widely utilized:

1) White pigments – talcum, zinc oxide, kaolin, titanium dioxide
2) Inorganic pigments, e.g., titanium dioxide, iron oxide, ultramarine, manganese violet, or chromium oxide
3) Organic pigments, e.g., Quinoline Yellow, D&C Red 6/7, Brilliant Blue FCF
4) Nacreous or pearlescent pigments (producing a pearl-gloss effect), e.g., mica, titanium dioxide-coated mica, iron oxides-coated mica, (nacreous pigment; → Pigments, Inorganic, Chap. 4.3.1.3.), bismuth oxychloride.

Colored pigments should have a particle size of 50 – 100 µm to prevent them from penetrating into deeper layers of the epidermis [86].

All approved colorants have been tested for their compatibility with the intended application (see, for example, the German Cosmetics Statutory Regulation, KVO). Additional regulations apply with respect to heavy-metal content, ancillary colorants, and starting materials.

10.3. Production

Emulsion bases are prepared as described in Chapter 3.

For production of *emulsion bases* the pigments have to be dispersed homogeneously in the water or oil phase of the emulsion before the emulsifying process is started. The process chosen is depending on the type of formula. The further production stages are similar to those described in Section 3.6.

For the production of *powders* color and pearl pigments as well as powdery raw materials such as talcum and zinc oxide are mixed and milled until the phase is homogeneously dispersed. Oils which have a binding capacity for the powder are then added and the whole phase is mixed again until uniform. The powder is subsequently pressed into godets.

For the production of *lipsticks* oils and waxes are melted in a vessel. Then predispersed color pigments are added to the hot phase and stirred until uniform. This bulk is filled into molds and cooled down quickly. The lipstick bullets are then ready to be filled into the lipstick mechanism.

11. Sunscreens

Sunscreens in the broadest sense provide protection against the harmful effects of light (i.e., electromagnetic radiation with a wavelength of between 1 and 10^6 nm) [87, 88]. In the technical and industrial sector they are used to protect materials such as plastics or other products that can be discolored or decomposed by light (→ Plastics, Additives, Chap. 3.).

They are also of significant economic importance. In Germany, for example, annual production value exceeds 100×10^6 DM, and involves 35 producers [89]. In 1991, the annual production value for Europe was ca. $\$954 \times 10^6$ and by 1995 is expected to reach ca. $\$1130 \times 10^6$ [90].

Direct damage due to light is restricted largely to the skin (including the hair and nails) and the eyes. Those light wavelengths which, on account of their high quantum energy, preferentially initiate photochemical reactions in body constituents are absorbed in the outermost layers of the body. The effects of light can be divided into four main groups:

1) *Acute Skin Damage.* Sunburn (erythema) with subsequent post-inflammatory (indirect) pigmentation and regenerative thickening of the horny layer ("sun callus"). Ultraviolet B radiation (UV-B, 280 – 315 nm) with maximum effect at ca. 297 nm is mainly responsible for sunburn. Since the lower wavelength limit of terrestrial sunlight is between 295 and 305 nm, the erythema maximum of sunlight is somewhat higher (300 – 310 nm). In the medical and industrial sector, for example in UV sterilization or materials testing, protection against ultraviolet C (< 280 nm) from artificial UV sources is also important. UV-C also produces erythema, but has a smaller penetration depth.

2) *Chronic Skin Damage.* Premature skin aging with elastotic degeneration of connective tissue, formation of precancerous tumors and, ultimately, malignant tumors (basal cell carcinomas, spinocellular carcinomas, and possibly a type of melanomas). UV-A (315 – 390 nm), UV-B, and probably also the shorter-wavelength visible light are most important in the formation of such tumors on account of their substantially higher penetration depth.

3) *Light-Induced Skin Disorders.* These include exogenous or endogenous dermatoses, such as xeroderma pigmentosum or phototoxic and photoallergic reactions. UV-A is generally a more important causative factor than other light wavelengths.

4) *Light-Induced Ocular Damage.* Visible and UV light may affect the conjunctiva, retina, and lens (cataracts). The eyelids generally provide sufficient protection against visible light, but artificial protection must be used to shield the eyes against UV wavelengths. In recent years, the field of ophthalmological sunscreen preparations has largely been ignored as a result of the development of suitable protective glasses, so this group of sunscreens is not discussed here.

11.1. Composition

A light-protective effect is achieved by producing a layer over, on, or in the horny layer (stratum corneum) of the skin. This layer protects the living cells in the epidermis from the damaging components of light by reflection, scattering, or absorption. The disruption of photochemical primary and secondary reactions in the skin has up to now been exploited only in counteracting light hypersensitivity caused by disturbances in porphyrin metabolism: internally administered β- carotene is employed as a radical scavenger.

Clothing has a major light-protective action on the skin. The color of the clothing has little effect, whereas its thickness and nature, and the condition of the textile fibers, play a decisive role. Rough natural fibers, including artificial silk (rayon), have a substantially greater light-protective effect than the smoother synthetic fibers. Either inorganic pigments, (e.g., zinc oxide, or titanium dioxide), micabased pigments, or more recently, micronized pigments, are used as sunscreens on and in the horny layer. They act as "physical" light filters, mainly by reflection and scattering. When used in large amounts, they have the disadvantage of forming a conspicuous layer on the skin. For this reason light filters that act by absorbing specific wavelengths ("chemical" light filters) have so far been most important. Employed in a suitable base, they penetrate the outer layers of the stratum corneum, producing a layer 5 – 30 µm thick that specifically absorbs UV-B and possibly also UV-A light. A great many substances with maximum absorbances from 300 – 310 nm (for UV-B) or 330 – 360 nm (for UV-A) are possible candidates for use as UV filters. However, the number of compounds tested or actually used is still very small (Table 1) due to the fact that most potentially suitable substances are either too expensive or too toxic. Special technological requirements are also placed on UV filters, the most important being light stability and the absence of marked fluorescence in the visible region. Suitable substances must penetrate as little as possible into the living skin (epidermis), and should display a certain degree of "substantivity" with respect to keratin (analogous to the substantivity of a dye).

Table 1. Light-protective substances, tested or in actual use

Name	CAS registry no.	formula	Other name	Listed in CTFA [a]	Listed in Blaue Liste [b]	Listed in INN [c]
UV-B filtering substances						
4-Aminobenzoic acid	[*150-13-0*]		Colipa S 1	PABA	UV 530	
2,3-Dihydroxypropyl-4-aminobenzoate	[*136-44-7*]		Colipa S 6	glyceryl PABA	UV 532 (e.g., Escalol 106)	
2-Ethylhexyl 4-dimethyl-aminobenzoate	[*21245-02-3*]		Colipa S 8	octyl dimethyl PABA	UV 535 (e.g., Escald 507, Eusolex 6007, Padimate 0, Uvasorb DMO)	
Ethyl 4-[bis((2-hydroxy-propyl)amino]benzoate	[*58882-17-0*]		Colipa S 2	ethyl dihydroxy-propyl PABA	UV 537 (e.g., Amer-screen P)	Roxadimate
2-Ethylhexyl 4-methoxy-cinnamate	[*5466-77-3*]		Colipa S 28	octyl methoxy-cinnamate	UV 445 (e.g., Absol EHM, Neo-Heliopan AV, Parzol MCX, Sunarome OMC)	
2-Ethylhexyl salicylate	[*118-60-5*]		Colipa S 13	octyl salicylate	UV 322 Sunarone (e.g., Heliopan)

Ethylpoly(oxyethylene) 4-{bis-[2-hydroxyethyl)poly(oxyethylene)]amino}benzoate	[*116242-27-4*]		Colipa S 3	PEG-25-PABA	UV 539 (e.g., Lusanthan 25, Uvinul P25)
3-(4-Imidazolyl)acrylic acid	[*104-98-3*]		Colipa S 46	urocanic acid	UV 823 (e.g., urocaninic acid)
Isopentyl 4-methoxycinnamate	[*71617-10-2*]		Colipa S 27	isoamyl *p*-methoxy cinnamate	UV 444 (e.g., Neo-Heliopan 1000)
4-Isopropylbenzyl salicylate	[*94134-93-7*]		Colipa S 16	isopropylbenzyl salicylate	UV 328 (e.g., Megasol)
α-(2-Oxo-3-bornylidene)-toluene	[*36065-10-8*]		Colipa S 61	3-benzylidene camphor	UV 121 (e.g., Ultracyd)
α-(2-Oxo-3-bornylidene)-4-toluene sulfonic acid	[*56039-58-8*]		Colipa S 59		UV 124 (e.g., Mexoryl 5L)
α-(2-Oxo-3-bornylidene)-*p*-xylene	[*36861-47-9*]		Colipa S 60	4-methylbenzylidene camphor	UV 122 (e.g., Eusolex 6300)

Table 1. (Continued)

2-Phenyl-5-benzimidazole sulfonic acid	[*27503-81-7*]		Colipa S 45	phenylbenzimidazole sulfonic acid	UV 854 (e.g., Eusolex 232, Neo-Heliopan, Hydro, Novantisol)	
3,3,5-Trimethylcyclohexyl salicylate	[*118-56-9*]		Colipa S 12	homosalate	UV 324 (e.g., Filtrosol, Homomenthyl salicylate)	Homosalate
N,N,N-Trimethyl-α-(2-oxo-3-bornylidene)-*p*-toluidinium methylsulfate	[*52793-97-2*]		Colipa S 57		UV 127 (e.g., Mexoryl SK)	
2,4,6-Tris{4-[(2-ethylhexyl)-oxycarbonyl]-phenylamino}-1,3,5-triazine	[*88122-99-0*]		Colipa S 69	octyl-triazone	UV 536 (e.g., Uvinul T 150)	

Table 1. (Continued)

UV-A filtering substances						
1-(4-*tert*-Butylphenyl)-3-(4-methoxyphenyl)-1,3-propanedione	[*70356-09-1*]			butyl methoxydibenzoylmethane	UV 664 (e.g., Parsol 1789)	Avobenzene
1-(*p*-Cumenyl)-3-phenyl-1,3-propanedione	[*63250-25-9*]		Colipa S 64	isopropyl dibenzoylmethane	UV 653 (e.g., Eusolex 8020)	
5-Benzoyl-4-hydroxy-2-methoxybenzene sulfonic acid	[*4065-45-6*]		Colipa S 40	benzophenone-4	UV 623 (e.g., Uvinul MS-40, Uvistat 112)	Sulisobenzone
2-Hydroxy-4-methoxybenzophenone	[*131-57-7*]		Colipa S 38	benzophenone-3	UV 613 (e.g., Cyasorb UV 9, Eusolex 4360, Neo-Heliopan BB, Uvinul M-40, Uvistal 24)	Oxibenzone
2-Hydroxy-4-methoxy-4′-methylbenzophenone	[*1641-17-4*]		Colipa S 39	benzophenone-10	UV 614 (e.g., Uvistat 2211, Uvistat L)	Mexenone
3,3′-(1,4-Phenylidenedimethine)bis(7,7-dimethyl-2-oxobicyclo(2,2,1)heptane-1-methane sulfonic acid	[*90457-82-2*]		Colipa S 71		UV 135 (e.g., Mexoryl SX)	

11.2. Evaluation

Determination of Protection against Erythema (UB-B Protection). In most countries sunscreens are classed as body care agents (skin care products) or cosmetics, although in the United States they are regarded as over-the-counter drugs. This classification appears justified because sunscreens, in contrast to most cosmetics, must have an objectively assessable effect.

The *mean protection factor* proposed by R. SCHULZE [94] was adopted as a scale for objective evaluation a few years after its publication in 1956. This factor is defined as the arithmetic mean of individual protection factors measured on of at least twenty test subjects with skin types representative of those expected for subsequent users. The individual protection factor is determined by measuring the light dose (exposure time) that produces a defined erythema in the untreated skin of a test subject. At the same time this measurement is also made on skin treated with the test product. The protection factor is the ratio of these two exposure times:

$$\text{Protection factor} = \frac{\text{MED}_{\text{Prot.}}}{\text{MED}_{\text{Unprot.}}}$$

MED = exposure time required to produce a specific erythema reaction
Prot. = for protected skin
Unprot. = for unprotected skin

If, for example, an exposure time of 2 min with the chosen light source (sun or lamp) is required to produce erythema in unprotected skin, and an exposure of more than 8 min is required to produce a recognizable erythema in the protected skin after ca. 24 h, the protection factor for the test subject and the test preparation is 4. In practice this means that, after application of the test product, sunbathing time can be increased roughly four-fold before sunburn becomes apparent.

Measurements are conducted according to fixed protocols (e.g., DIN 67 501 or FDA). The test subject's body is divided by horizontal adhesive strips into areas of skin measuring ca. 10×150 mm. Every other area is then treated with a specific amount of the test preparation. These horizontal areas are next divided by vertical adhesive strips into areas of ca. 1 cm^2. After the onset of exposure to radiation of a specific wavelength the vertical rows of skin regions are covered successively from left to right at specific time intervals. The adhesive strips are subsequently removed, and after ca. 24 h the erythema threshold (the first region with a defined erythema test reaction) is identified and associated with the exposure time required to produce this reaction.

The radiation source, the composition of the group of test subjects, and the accuracy of the erythema threshold readings are the most important factors in assuring reproducibility of the results.

Sunlight would, of course, be the most reliable source. However, this is impractical because the necessary exposure time (minimum erythema dose, MED) is seldom less than 10 min even for sensitive skin. Furthermore, the total amount of available sunlight seldom reaches 15 times the MED on any one day, even in the vicinity of the equator. For these reasons (higher) protection factors cannot be determined in sunlight. A wide range of artificial light sources is therefore used instead. The results will approximate practical conditions (i.e., exposure to sunlight) only if the relationships between the light wavelengths and intensities (UV-B, UV-A, visible, and near IR) correspond to those prevailing in sunlight. With this proviso, it appears to be of relatively minor importance whether the radiation source displays a continuous or a band spectrum.

Methods used in Europe (DIN), the United States (FDA), and Australia (Standards Association of Australia, SAA) to determine the protection factor differ in the choice of radiation source (and thus in the spectral composition of the light) [95], [96]. Comparison of the values obtained by these methods is further complicated by the fact that different amounts of preparation are applied, and MED determinations are sometimes conducted on widely separated regions of the skin (possibly even with different light sensitivities), or on different days. This means, for example, that values determined by the United States method are generally higher, particularly with powerful sunscreens, than those obtained with the DIN method.

As a result of the tendency to proclaim ever higher protective factors in product advertisements, coupled with problems in reproducibility, attempts are being made to replace numerical protection factors with more straightforward protection *categories*, which are in turn based on the experimentally derived numerical values:

Protection factor	Classification
2–4	weak
4–7	moderate
7–10	strong
>10	very strong (sun blocker)

The practical significance of such a classification is illustrated in Figure 2 [97]. This particular assignment of sunscreen classes reflects more clearly the wish of the user to develop a "sporty" suntan than to follow strict medical considerations.

Those areas of the skin regularly exposed to sunlight, i.e., the face, neck, and the back of hands, are protected best with a sun blocker, since this is the only way of achieving effective prophylaxis against skin aging and light-induced cancer.

Determination of Protection against UV-A. Protection against UV-A has become increasingly important. The starting point in the development of "broad-spectrum sunscreens" (preparations effective against both UV-B and UV-A) was a search for "therapeutic sunscreens," since UV-A often plays an initiating role in light-induced skin disorders. Interest in broad-spectrum sunscreens for preventing light-induced skin aging and its consequences increased along with knowledge about the importance of UV-A in damage to the deeper layers of the skin (i.e., connective tissue and blood vessels in the dermis).

Experimental testing of such prophylactic action is impossible, however, because the skin changes of interest develop only over the course of years. Indirect methods must therefore be used to detect UV-A protective action. Use in this context of subjects with a pronounced (pathological) skin reaction to UV-A exposure is obviously excluded, not only for ethical reasons, but also because only very few such patients exist. Testing based on UV-A-induced erythema is generally impractical as well, because of the very high UV-A doses required.

Objections also exist to evaluation via the inhibition of UV-A-induced "direct pigmentation" [99], which involves photooxidation of the skin pigment melanin. This pigment is seldom present in sensitivity type I subjects (Fig. 2), and is only present in small amounts in type II subjects. Such tests are therefore possible only on skin types III and IV, which are rare among northern Europeans, and thus hardly representative. Furthermore, the melanin that is photooxidized by UV-A is located predominantly in the epidermis, so it is almost impossible to draw any conclusions about the extent to which UV-A may have penetrated the dermis.

An alternative indirect method, namely UV-A-induced photosensitization in the presence of an appropriate sensitizing agent, is now the most common approach to determining protective effects against UV-A. The primary photosensitization reaction takes place mostly in the dermis, and manifests itself in an erythematous reaction for which a threshold time can be measured, as in the case of UV-B-induced erythema.

This measurement can be performed by treating the whole test region of the skin with a 0.15 % solution of the photosensitizer 9-methoxy-7*H*-furo(3,2-*g*)(1)benzopyran-7-one (8-methoxypsoralene [*298-81-7*] in 30 % 2-propanol. After evaporation of the solvent, the skin is divided into areas as in the UV-B method (see above). Illumination with black-light tubes (e.g., Philips TLK 40W D9N) begins 30 min after application of the photosensitizer. The erythema reaction, which is pathogenetically quite different from UV-B erythema, can be measured, at the earliest, after 48 h. A UV-A protective factor is assigned in the same way as in the UV-B method. Investigation of >100 products showed protection factors significantly above 10 for certain dibenzoylmethane derivatives.

Determination of Water Resistance. The need for water-resistant sunscreens results from the fact that many preparations rapidly lose their effectiveness in the presence of sweat and during swimming and water sports. This is dangerous for swimmers subject to high solar intensity since UV-B radiation passes almost unattenuated through water.

There is no universally accepted test method for water resistance. Investigations have shown that the rinsing of test areas on seated subjects

Figure 2. Nomogram for choosing a sunscreen [97], taking into consideration the sensitivity of an individual's skin and the intensity of sunlight [98].

with tap water at 21 °C for 20 min provides reproducible results. Seawater generally produces higher water-resistance values than tap water, presumably because of a salting-out effect in the sunscreen film on the skin surface.

Figure 3. Dependence of light-protective action on the cosmetic base

11.3. Effectiveness and Production

Several factors may be responsible for the observed discrepancy between physically measured UV-absorbance values and biological protective action on human skin: the layer structure may differ from one preparation base to another, penetration of the filter substance into the horny layer may vary, and some filter substances may react with certain constituents in the horny layer.

Systematic investigations reveal connections between the filter substance, cosmetic base materials, and biological protective action which have so far not been satisfactorily explained. For example, dibenzalazine [*588-68-1*] (EusolexR 6653), previously used as a light filter, showed very different increases in protective action with increasing concentration depending on the base (Fig. 3). Similar results were obtained with 4-methoxycinnamates [100]. With emulsions the protective effect increases with the water content [101]. The very weak protective action of oils is easily explained, because oils do not form a homogeneous layer on the skin [102]. Figure 4

demonstrates that the protective effect increases more significantly with filter content if an oily microemulsion is used as the base instead of an oil. Diffusion of filter substance from the base into the horny layer appears to be an important factor.

Figure 4. Improvement in light protection when an oil base is replaced by an oily microemulsion: liposoluble 2-phenyl-5-methylbenzoxazole in oil (a) and a transparent emulsion (b) [101]

Virtually all base types used in the body care sector lend themselves to sunscreen preparation, the most popular being emulsions. The precise formulations of such products are generally proprietary secrets. For information on generic formulations see [87]. Reference should be made to [103–105] for details of analysis.

11.4. Toxicology and Environmental Protection

An important reason for the small number of filter substances currently in use is the requirement for detailed, comprehensive toxicological investigations, because sunscreen preparations are generally applied repeatedly, and over a large area of the skin. Even if the concentration of a given filter substance is only 5 %, 1 – 5 g of the substance would be applied to the skin in a single application of 20 – 100 g of finished product. Absorption of only 1 % of the applied filter substance implies an uptake of 10 – 50 mg by the body after a single application. The increasing popularity of "physical" light protection (see above) is therefore welcome on medical grounds, although micronized pigments must also be subjected to thorough toxicological testing.

From the medical standpoint, sunscreen application requires careful risk – benefit evaluation despite the proven value of these agents in preventing or reducing acute and chronic skin damage. This is particularly applicable to products for pediatric use and extremely active products. The regular application of strong sunscreens may also influence photosynthetic vitamin D formation [106], [107] and immunological processes in the skin [108], [109].

Weighing the risks and benefits is easiest when a sunscreen leads to undesirable skin reactions [110]. Allergic and photoallergic eczemas demand lifelong avoidance of the causative agents. In the case of a photoallergy this means avoiding dibenzoylmethane derivatives, which remain indispensable today as UV-A filters. Successfully avoiding a filter substance that has proved to be an eczematogen obviously requires awareness of its presence in a commercial preparation [111].

Finally, modern sunscreen toxicology requires raising the question of the impact of these products on the environment, especially in view of the large quantities of sunscreens available on the market (estimated production during 1991 in Germany alone was 5000 t [89]). It is therefore important to inquire into the ultimate fate of these materials – in chlorinated swimming-pool water, for example. Chlorination of the benzene ring of methoxycinnamates is certainly conceivable [112].

12. Stability Testing

Stability information supplied in conjunction with a particular product must be regarded as binding with respect to each individual production batch. For this reason the establishment of reliable stability parameters constitutes an important goal during the systematic development of a new cosmetic product.

Stability projections are always based on many individual test results obtained gradually over the entire course of product development. The overall procedure can be divided into the following stages:

1) Stress and induced aging tests

2) Long-term testing
3) Routine follow-up tests during production
4) Tests for the detection of the effect of changes introduced into the production process

All subsequent procedures, from the selection of test batches up to stability assessment, apply to each of the above stages. These are, however, of differing importance in the projection of stability of a product.

12.1. Storage Conditions

In establishing appropriate storage parameters, a clear distinction must be made among conditions applicable to stress and induced aging tests, long-term tests, routine follow-up tests, and tests related to changes during manufacture.

Whereas the storage-temperature and humidity conditions for long-term testing are normally based on typical climatic conditions in the countries in which a product is to be marketed, stress and induced aging tests are usually performed on samples stored at minimum and maximum temperatures and/or humidity levels for the markets of interest, or under constantly varying conditions. Storage under diffuse daylight conditions or with exposure to ultraviolet radiation can also affect product quality, especially with transparent or translucent packaging. Stability testing is sometimes necessary under these conditions as well.

12.2. Test Methods

The choice of stability-testing methods is usually based on scientific knowledge of the products in question as well as on manufacturing experience. Methods routinely invoked can be divided into several categories.

Organoleptic Studies. Organoleptic (sensory) studies are normally conducted to check the following product characteristics as a function of storage time and storage conditions: appearance, odor, and in-use behavior.

Package Compatibility Tests. Some cosmetic formulations are capable of reacting with components of the packages in which they are stored. Organoleptic studies, as well as tests for loss of product weight and physical changes of the packaging material (distortion, softening, or hardening), are useful in this context [65]. The following phenomena are frequently monitored: (1) water or oil leakage, (2) phase separation, (3) changes in color, (4) changes in odor, (5) weight loss (especially in plastic containers), and (6) physical changes in the packaging material.

Physicochemical Studies. The long list of scientific publications dealing with physicochemical characterization of cosmetic formulations makes it worthwhile to consider separately the study of cosmetic emulsions, detergent-based products, gels, and sticks [113–116].

Emulsions. Instability of a cosmetic emulsion is usually characterized by increased flocculation and coalescence of the dispersed phase, followed by creaming, which may lead ultimately to phase separation. Many attempts have been made to characterize these phenomena by physical or physicochemical means. The methods used include:

1) Microscopic analysis of age-dependent changes in droplet size distribution [117]
2) Study of time-, temperature- and force-dependent induction of phase separation through centrifugation, especially as a function of storage time [118], [119]
3) Rheological characterization on the basis of flow curves, oscillation measurements (frequency sweep, strain sweep, time sweep, temperature sweep), and creep studies all of which are capable of distinguishing between stable and unstable emulsions [120–122]
4) Thermoanalysis based on differential scanning calorimetry and thermogravimetry [123]

Use of the following techniques has also been described: laser scattering [124], [125], pulsed nuclear magnetic resonance [126], turbidometric measurements [127], and measurement of changes in conductivity or in dielectric properties [128–131].

Detergent-Based Cosmetics. Apart from rheological characterizations, the detection of color changes and changes in distribution of the opacifier(s) employed are often important in the study of detergent-based cosmetics. Inhomogeneity

of the opacifier can be detected by examining the following parameters [132]: fluctuation in reflected light intensity, turbidity, and gloss. Changes in color are usually determined by simple photometric techniques.

Gels. Gels are also subject to rheological changes, but color changes and, in the case of clear gels, increasing turbidity can cause problems. Methods useful for monitoring color changes and turbidity have already been discussed.

Sticks. Deodorant sticks or lipsticks may exhibit any of the following undesirable characteristics after storage at certain temperatures: deformation, change in adhesiveness with respect to the cartridge material, crystallization, or leakage of oil or water.

Microbiological Studies. All cosmetic products are subject to microbial contamination. Aqueous cosmetics may promote the growth of yeasts, molds, and bacteria unless appropriate preservatives are included in the formulations. Dry cosmetics (mascara, eye shadow, etc.) are also subject to contamination through repeated use. Testing the efficacy of preservatives is very important in assuring the safety and stability of cosmetic products. Various test methods have been suggested for estimating microbial stability [133–136].

Chemical Studies. For products containing active ingredients, quantitative assay of these components is worthwhile for various storage periods during the overall test period. Autoxidation and hydrolysis are the most general problems encountered during storage. Quantitative study often makes it possible to predict rates of potential chemical changes during storage.

13. In Vitro Compatibility Testing

13.1. Introduction

Body care agents and toiletries are found in virtually every household. They are used often, sometimes over long periods of time and in large quantity and for a wide range of purposes on the skin, hair, and mucous membranes. Some remain in contact with the body for prolonged periods and at varying levels of intensity. For this reason, consumers expect the products to be safe when used according to instructions and for the intended purposes. The obligation on the part of legislators and cosmetic producers to protect the consumer is reflected in a comprehensive legal framework. For example, several laws and regulations apply to cosmetics distributed in Germany. These include the Chemicals Law with respect to raw materials evaluation, the Food and Consumer Goods Law, and the Cosmetics Regulations (including several appendices), which are based on the European Cosmetic Directive and its amendments [127–142], as well as recommendations from the Federal Health Office and the Scientific Committee on Cosmetology of the European Community [143], [144]. The combination of this binding legislative framework with extensive public discussion on the banning of animal experiments, particularly for cosmetics, has led to a serious dichotomy that is forcing a reexamination of conventional means of ensuring product safety.

Against the background of the manufacturers' responsibilities on the one hand and consumer expectations of product safety on the other, producers of cosmetics are making concerted attempts to develop new conceptual approaches toward satisfying the increasingly stringent requirements for the safety of their products, but doing so without recourse to animal experiments on the finished products.

13.2. Test Methods

In several EC countries and in the United States, producers are engaged in intensive efforts to validate test methods that do not involve animal experimentation, but still permit adequate evaluation of finished products, especially in terms of local compatibility with the skin, hair, and mucous membranes. Much current emphasis is on new tests for ocular mucous membrane and skin irritation. Numerous alternative test methods have been proposed [145], and the problem now is to select those that best satisfy important criteria, including ease of handling and processing, reliability (i.e., applicability to all relevant groups of materials and products), sensitivity, and reproducibility. Through joint efforts on the part of those responsible, and with support from

bodies such as the European Center for the Validation of Alternative Methodologies (ECVAM, Italy), the Center for Documentation and Evaluation of Substitutes and Supplements for Animal Testing (ZEBET, Germany), the Fund for the Replacement of Animal Testing in Medical Experimentation (FRAME, United Kingdom), and the Center for Alternatives to Animal Testing (CAAT, United States), access is now available to various means of validating these alternative methods [147–149], which must also be accepted by the regulatory bodies involved. International studies [146], [150–152] have led to the following methodological approaches:

1) *Biochemical and physicochemical properties* of constituents and products can be used to evaluate specific interactions [150].
2) *Cytotoxicity tests* on isolated blood cells [147], [149] or permanent cell lines [145], [152], [150] are extremely sensitive and, for relevant classes of substances, show good correlation with acute ocular irritation. Another advantage of these processes is that they can be partly automated.
   Furthermore, cytotoxicity tests have been successfully used for in vitro photoirritation testing. As a result of a joint EU/COLIPA validation study of in vitro phototoxicity tests the 3T3 Neutral Red Uptake Phototoxicity Test has been validated [150], [153], [154], [156] and proposed by the Scientific Committee for Cosmetic Products and Non-food Products (SCCNFP) as the standard method for testing the UV light absorbing cosmetic ingredients or mixtures of ingredients for phototoxic potential [157], [158].
3) *Hen egg tests on the chorioallantosis membrane* (HET-CAM) [155], [157]. Macroscopic changes caused by the action of mild to moderate eye irritants are readily visible in the sensitive vascular system of incubated chicken eggs, appearing as dilation and enhanced permeability of the small blood vessels [155].
4) *Organotypical skin cultures* and *excised skin* are particularly valuable for answering questions involving the skin barrier. For in vitro dermal absorption/penetration studies with excised skin standardized methods are available [159], permitting the evaluation of numerous biological parameters. Three-dimensional skin cultures have also been used and are currently prevalidated for in vitro skin irritation and photoirritation testing. Such techniques are suitable for substances that are unstable under UV-A or UV-B radiation and that, as a consequence, might induce irritation [161].
5) *Skin sensitization potentials* cannot yet be examined in vitro. Currently, research on the suitability of cytokines (especially IL-1β) as endpoint for a discrimination between sensitizers and irritants and on biotransformation (prohapten activation) is carried out in projects sponsored by COLIPA/SCAAT and ECVAM.

Known toxicological safety data must be used in conjunction with results of the in vitro tests to provide a basis for evaluating a complete cosmetic preparation prior to dermatological testing. Every product undergoes final evaluation in dermatological tests consistent with good clinical practice (GCP), a prerequisite for introducing the product onto the market.

14. Economic Aspects

Body and skin care products have always been – and are now perhaps even more than ever – very important for bodily well-being. Relatively precise figures are available for the cosmetic markets in the United States, Japan, and Europe, as shown in Table 2. Market volumes for the United States and European markets are comparable. If its smaller population is taken into account, Japan also appears prominently in the picture. In Europe the largest markets in the cosmetics sector are in France, Italy, and Germany. Face care products play a predominant role in every country. However, Japan, with an annual turnover of more than 6×10^9 €, leads in the facial products sector by a wide margin.

15. Legal Aspects

Cosmetics are regarded as consumer products, and are therefore subject to legal provisions that protect the consumer against misrepresentation and damage to health. In Germany, for example, cosmetics are defined as preparations used externally on persons for purposes of cleansing,

Table 2. The international market for cosmetic products

	Market volume, 10^9 €		
Product category	United States	Japan	Europe
Skin and face care	5.6	6.8	8.7
Body care	3.8	1.0	4.7
Hair treatment agents	5.5	4.2	6.2
Perfume	2.4	0.2	3.2
Decorative cosmetics	3.2	3.1	3.3
Other	2.6	1.4	4.1
Total	23.1	16.6	30.3

care, or influencing appearance or body odor (§ 4 of the Food and Consumer Goods Law, LMBG [139]). In 1976, these provisions were expanded by the introduction in all EC states of the EC guideline "Cosmetic Agents" [140]. In Germany this guideline and the LMBG were finally combined in 1977 to form the Cosmetics Statutory Regulation (KVO) [138], which lists forbidden constituents as well as substances permitted with certain restrictions (e.g., preservatives, coloring agents, and UV filters). A few EC member states have regulations that deviate from EC guidelines. In France and Spain, for example, both qualitative and quantitative information must be provided for publicly marketed active constituents. It is not legally necessary in Europe to label the ingredients on the package, but manufacturers are increasingly doing so nonetheless. In the United States, a distinction is made between cosmetics and over-the- counter (OTC) drug products. As in the EC, certain constituents such as UV filters and coloring agents are explicitly included in lists of regulated substances. OTC preparations must also satisfy certain additional requirements, the details of which depend on the product category. According to U.S. law, all constituents of a cosmetic formulation must be listed on the package [160].

In Japan all cosmetic constituents are included in official registry lists. Almost 600 substances are described in great detail in book-length publications covering specifications, production, and intended use. Other raw materials are listed in the Japanese Cosmetic Ingredient Dictionary (JCID) [161]. All new substances must be reported to the relevant authorities. Depending on the product type and intended use, cosmetics are subdivided into 78 different groups, further distinguished according to whether they are cosmetics or quasi drugs. The latter are permitted to contain only active constituents that have been authorized in this category. Legal provisions in many countries are based on laws applicable in the United and the European Community. For example, regulations in Austria, Norway, and Turkey are similar to the EC guidelines. In Latin America and Southeast Asia, cosmetics must be registered with the appropriate authorities. Other countries such as Sweden require that cosmetic products be reported to a national poisons office before they are introduced on the market.

1. Introduction

In everyday language, soaps are sodium and potassium salts of fatty acids: saturated or unsaturated aliphatic carboxylic acids, most of which occur in nature (→ Carboxylic Acids, Aliphatic; → Fatty Acids). The acids almost always have unbranched carbon chains ($>C_8$), exhibit surface-active properties in the form of their alkali salts in aqueous solution, and constitute classical anionic surfactants (→ Surfactants). Salts of the same acids with other metals are called metallic soaps. These possess considerably different physicochemical and industrial properties and, for this reason, are discussed separately (→ Metallic Soaps).

2. Historical Aspects

The history of soap begins with our forefathers learning to prepare a type of washing paste by melting fat together with wood ashes. An early recipe for soft soap is recorded on clay tablets from Mesopotamia, the region between the Euphrates and Tigris, dating to ca. 2500 B.C.

In 79 A.D. PLINY the Elder asserted in his *Historia Naturalis* that soap was invented by the Gauls, but the Gauls most probably acquired the recipe from the Egyptians by way of the Phoenicians, because soap was already known in Egypt (as *Andjir*) in Coptic times, during the first century A.D. Teutonic peoples later adopted this soap product from the Gauls and improved upon it continuously. According to PLINY, "sapo" was prepared both as a liquid potassium-soap product and in a solid form. Especially high quality soaps were obtained from goat tallow and wood ashes.

Teutonic soap was a popular export article, and was used in Rome also as a hair dye and pomade. Soap from Germania was highly praised by GALEN, the personal physician of Emperor MARCUS AURELIUS, in the second century A.D. He was apparently the first to recognize the value of soap as a washing and cleansing agent. However, GALEN's propaganda success was limited. While the men took his advice, Roman ladies were sceptical, and continued to wash with plain water. In the third century, the Roman Emperor SEPTIMIUS SEVERUS had greater psychological success in promoting soap. He followed the counsel of his famous doctor SERENUS SAMMONICUS, advising women around him to cleanse their faces with crushed herbs dissolved in oil as a way of making themselves more at-

10.1002/14356007.a24_247

tractive to men. These examples show, incidentally, that even in early history cosmetics played a significant role in peoples' lives.

In 385 A.D. THEODOROS PRISCIANUS recommended using soap for the washing of hair. He also provides the first record of the "saponarius", or soap-maker.

Domestic soap-making was broadened to include active trade in soap toward the end of the eighth century under the emperor CHARLEMAGNE, and soap-making became a recognized occupation within the imperial domains. During the ninth century, the Spanish spread the art of soap-making into the lands surrounding the Mediterranean, especially in the areas of Marseilles, Venice, Genoa, and Alicante.

In the fourteenth century, German soap-makers united to form their own guilds (Augsburg, 1324). The soap-maker's trade was frequently combined with that of the candlemaker. A soap-maker's apprentice spent three years in training before being allowed to take the apprentices' final examination. The premium for an apprenticeship was 100 Thaler. If this premium could not be paid, the apprenticeship period was increased to six years. Before taking the master's examination, journeyman soap-makers were required to perfect their skills by traveling from city to city, finally preparing their own batch of soap. The composition of the soap was deemed worthy of a master craftsman if it took on a speckled appearance in the kettle.

As early as the fifteenth century, Portuguese and Spanish missionaries introduced soap into Japan. Presented as a precious gift to the rulers, it was hoped that the soap would invoke a sympathetic response toward missionary work in their territories [1].

The art of soap-making reached its high point in the period before the Thirty Years' War, but the general spread of soap as a commodity occurred only later. For a long time the use of soap remained restricted, because it was regarded as a luxury item. Only after the introduction of large-scale soda production (by the Le Blanc and Solvay processes) and widespread import of fats and oils from the tropics was the foundation laid for the industrial production of soap, permitting it to become a common consumer article.

Although soap-making has not been practiced as a skilled trade for some time, fine soap today is more varied and inexpensive than ever before. Indeed, in the technically advanced twentieth century it is impossible to imagine everyday life in the absence of soap. Even at the beginning of the twenty-first century, the future of the "good old soap" seems quite secure.

A wide assortment of soap products has been developed during the course of time. Based on use and appearance, it is possible to distinguish the following product groups:

1) Toilet soaps (including special soaps)
2) Hard soaps, soap flakes
3) Shaving soaps or creams
4) Soft soaps
5) Liquid soaps

Twenty years ago, hard soaps, soap flakes, and soft soaps were still very important in the areas of textile washing and general household cleansing. Today, their place is frequently taken by modern powdered and liquid household detergents and cleansers (→ Laundry Detergents), and the use of liquid soaps in dispensers remains rather restricted.

By contrast, toilet and fine soaps have maintained an undisputed place in the market. Cream or cosmetic soaps, luxury soaps, deodorant soaps, children's soaps, skin-protecting soaps, and special medicinal soaps are all included in this category. All are derived from a high-quality soap base which, by the addition of various active ingredients, can be endowed with specific grooming, cosmetic, or deodorizing properties. Indeed, almost unlimited variations with respect to form, color, and fragrance satisfy almost every imaginable consumer desire [2].

3. Raw Materials

Numerous naturally occurring plant and animal fats and oils can be used as the starting materials in soap-making, especially beef tallow, palm oil, coconut oil, and palm kernel oil. Fatty acid compositions for these neutral fats are given in Table 1. Peanut oil and olive oil as well as lard are also utilized to a lesser extent. Table 2 provides typical carbon chain-length distributions for fatty acids in soap itself. The fatty acid composition of the soap-making materials varies depending on the intended purpose of the soap. Normally, 75 – 85 % beef tallow and 15 – 25 %

coconut oil constitute the main components in soap-making. C_{12} and C_{14} soaps lather quickly, but they produce an unstable, coarse-bubble foam. On the other hand, C_{16} and C_{18} soaps lather rather slowly, but lead to a stable, fine-bubble foam. Apart from fatty acid composition, the quality of a soap is also a function of the purity of the raw materials, their physical and chemical characteristics, and their color and odor.

Triglycerides are the most important starting materials for the making of soap (Fig. 1), because they are easily transported and are not subject to quality losses during transport. Free fatty acids may also serve as raw materials, but the distillates employed must be as fresh as possible. Such distillates are not always available in a suitable quality and at a reasonable price. Transport and storage factors play an important role in the soap industry. No general answer can be given to the question of whether triglycerides should be preferred over free fatty acids as starting materials for the production of soap, but recovery of the valuable byproduct glycerol must be a part of the consideration (see Section 4.1.).

The use of fatty acid methyl esters as soap-making materials has also been discussed, and recently put into practice as well (e.g., by the Lion Corp., Japan); like triglycerides, these substances can be transported and stored without any reduction in quality. As intermediates in the synthesis of fatty alcohols (→ Fatty Alcohols, Chap. 2.3.3.1.), alkanolamides, and ester sulfonates, these compounds are associated with substantial production capacities, which are constantly increasing. However, from a worldwide standpoint, such esters currently play only a minor part in the production of high-quality toilet soaps.

Sodium hydroxide is acquired primarily in the form of a 50 % solution from chlor-alkali electrolysis (→ Chlorine, Chap. 4.; Electrochemistry, Chap. 4.1.), as is potassium hydroxide. The soda sometimes required for the reaction with fatty acids is the usual anhydrous commercial product. Potassium carbonate is used in small amounts for the manufacture of soft soap, as is potassium chloride. In saponification, the ratio of caustic to fat (acid) is adjusted such that no more than a 0.05 % excess of caustic is present in the finished soap.

Apart from sodium hydroxide solution, sodium chloride (common salt, rock salt) is the most important inorganic auxiliary agent. To prevent the formation of unwanted greasy, insoluble, alkaline-earth soaps, the NaCl should contain minimal amounts of calcium and magnesium salts, a consideration that applies to potassium chloride as well.

Other additives and auxiliary agents are discussed elsewhere in the article.

Figure 1. Raw materials utilized in soap-making [3]

4. Production

In principle, the production of soaps comprises the following steps:

1) Production of a suitable soap base
2) Mixing and homogenization of the soap base with additives, such as perfume oils, coloring matter, and skin-grooming substances (refatting agents)
3) Extrusion
4) Cutting to rough form
5) Shaping
6) Packaging

4.1. Basic Principles

In soap-making terminology, "saponification" is understood to mean simply the formation of soap. If a charge of suitable fats and oils is saponified with sodium hydroxide solution, the procedure is called "neutral oil saponification". If the charge consists of distilled fatty acids, the process is called "fatty acid saponification". The saponification of fatty acid methyl esters with sodium hydroxide solution is called "fatty acid

Table 1. Fatty acid compositions of the most important neutral fats used in soap-making (%)

	Coconut oil	Palm kernel oil	Palm oil	Beef tallow
Octanoic acid (caprylic acid)	6 – 9	3 – 10		
Decanoic acid (capric acid)	6 – 10	3 – 14		
Dodecanoic acid (lauric acid)	44 – 51	37 – 52		
Tetradecanoic acid (myristic acid)	13 – 18	7 – 17	1 – 6	2 – 8
Hexadecanoic acid (palmitic acid)	8 – 10	2 – 9	32 – 47	24 – 33
Octadecanoic acid (stearic acid)	1 – 3	1 – 3	2 – 8	14 – 29
Octadecenoic acid (oleic acid)	6 – 8	11 – 23	40 – 52	39 – 50
Octadecadienoic acid (linoleic acid)	1 – 3	1 – 3	5 – 11	1 – 5

Table 2. Typical carbon chain-length distribution of fatty acids in soaps (%)

Chain length	%	Chain length	%
C_8	0.5	C_{16}	24.6
C_{10}	0.5	C_{18}	5.6
C_{12}	7.3	C_{20}	56.5
C_{14}	5.0		

methyl ester saponification". The individual processes can be represented by the following equations:

1) Neutral oil saponification

$$\begin{array}{l} CH_2OCOR^1 \\ | \\ CHOCOR^2 \\ | \\ CH_2OCOR^3 \end{array} + 3\,NaOH \longrightarrow \begin{array}{c} R^1CO_2Na \\ + \\ R^2CO_2Na \\ + \\ R^3CO_2Na \end{array} + \begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array}$$

Neutral oil or neutral fat — Lye — Soap — Glycerol

R = fatty acid alkyl group

R = fatty acid alkyl group

2) Fatty acid saponification

b) Saponification

$$RCO_2CH_3 + NaOH \longrightarrow RCO_2Na + CH_3OH$$

Fatty acid methyl ester — Lye — Soap

Neutral oil and fatty acid saponifications have been applied successfully for decades, and lead to products of equivalent quality. This should not be surprising: the production of a perfect soap requires that the soap base be extremely pure and, above all, free of unpleasant side odors. In principle, it is irrelevant whether the necessary purification and washing operations are achieved by fat splitting and distillation of the split fatty acids or by saponification of the neutral fats to a soap base that is subsequently purified by repeated closing, salting out (opening), separation, and washing.

While the splitting of fats by steam with subsequent distillation of the fatty acids entails considerable expense, fatty acid saponification can be accomplished fairly easily with modern continuous processes. Moreover, processing the resulting glycerol water for the recovery of the

valuable glycerol is straightforward and environmentally friendly compared with the treatment of very salty lye from neutral oil saponification.

Both saponification processes can be conducted either discontinuously in steam-heated open kettles, analogous to the classical boiling process, or continuously in closed saponification systems. Saponification of fatty acid methyl esters is carried out in continuously operated, closed systems, because in this case economic and ecological factors require that methanol be recycled. Neutral oil saponification and fatty acid saponification give rise to soap bases with fatty acid contents $\leq$63 %.

Figure 2. Soap formation from neutral fats, plotted as a function of time (adapted from [5])

4.1.1. Saponification of Neutral Oils

In the saponification of natural oils and fats with aqueous sodium hydroxide (e.g., in kettle saponification) the triglyceride and caustic soda reactants are neither mutually soluble nor miscible. Achieving a satisfactory reaction rate requires intensive mixing, which is accomplished by emulsification. In practice, small amounts of soap form very rapidly through neutralization of the free fatty acids that are always present in fats. This soap then acts as an emulsifier. In this process a specific limiting concentration of sodium hydroxide must never be exceeded. This limit corresponds to the sodium hydroxide concentration above which dissolved soap precipitates in the form of flakes [4], rendering it no longer available as an emulsifying agent. Two groups of fats can be distinguished with respect to their limiting sodium hydroxide concentrations:

1) Soft fats, with a limiting sodium hydroxide concentration of 14 – 18 % (e.g., coconut oil, palm kernel oil)
2) Hard fats, with a limiting sodium hydroxide concentration of 4 – 6 % (e.g., beef tallow)

As suggested by Figure 2, the saponification of neutral oils comprises the following three stages [5]:

1) *Emulsion Saponification*. The process of saponification proceeds slowly until formation of a fat emulsion or dispersion is complete.
2) *Rapid Saponification.* The reaction rate increases as more soap is formed until a freeflowing liquid soap paste is produced. Vigorous reaction continues while most of the fat is transformed into soap.
3) *Final Saponification*. This reaction occurs in a homogeneous, pulpy mass.

In this final stage the reaction rate is so low that extended boiling with excess sodium hydroxide solution is required to saponify the last traces of fat. The viscosity of the reaction mixture is reduced as necessary by adjusting the electrolyte concentration. In practice, this requires adding sodium chloride, either as a solid or in solution. However, this "reduction" of the paste must be carried out very carefully, because too much electrolyte leads to a separation into two phases, where the upper phase contains most of the soap and the lower phase almost all the electrolyte. The nigre thus floats on the lye phase below, a phenomenon known as "salting out".

The nigre can be purified by repeated salting out, separation of the lye, and renewed closing, thereby reducing the electrolyte concentration. In the final operation, "fitting", addition of water and electrolyte produces a three-phase equilibrium state: neat soap, nigre, and lye. The neat soap is further processed and the precipitated nigre is either added to the next batch to assist in emulsification or it is processed separately.

4.1.2. Saponification of Fatty Acids

If appropriate fatty acid distillates are used as raw materials instead of oils and fats, the saponification step corresponds to a neutralization.

Here again, the presence of soap as an emulsifier is absolutely essential. In fatty acid saponification, a soda solution can be used instead of sodium hydroxide solution.

Figure 3. Flow diagam of the Lion E-S Process for the production of soap base

4.1.3. Saponification of Fatty Acid Methyl Esters

As mentioned previously, the saponification of fatty acid methyl esters must be carried out in a closed apparatus, because the methanol must be recycled.

Fatty acid methyl esters are obtained by transesterification of fats with methanol. The Lion E-S process, developed by the Lion Fat & Oil Co. in Tokyo, Japan [6], is illustrated schematically in Figure 3.

In the first step the fat charge is treated with methanol in the presence of an ion-exchange resin, resulting in esterification of the free fatty acids normally present. The second step is a transesterification with methanol in the presence of alkali, followed by recovery of excess methanol. The reaction mixture is then transferred to a continuously operated separator, where the phases are separated. The lighter phase consists of fatty acid methyl esters, and the heavier phase contains crude glycerol, some soap, and impurities from the oil. The methyl esters are saponified continuously with sodium hydroxide solution. The resulting crude soap is treated with steam to remove traces of methanol and then processed in the usual manner.

4.2. Industrial Production of Soap Bases

A generalized flow diagram for the industrial production of soap is provided in Figure 4. In principle, both batch and continuous processes can be used. Kettle saponification, a batch process, is described separately here for historical reasons.

4.2.1. Kettle Saponification

The classical boiling process with live steam in deep, open kettles or pans was for many decades the most important method of soap-making, and the process is still employed in some soap factories (Fig. 5). The pans are conical, cylindrical, or rectangular in shape. The most common type of pan is very wide, but relatively shallow in the cylindrical part, tapering to a deep cone. Inside the pan is a distributing ring introducing live steam, and sometimes a heating coil for indirect heating, together with a siphon and a swing pipe for removing the neat curd. The lye and nigre exit via a bottom valve at the point of the cone. The batch is mixed by the action of the steam.

Boiling kettles with stirrers have also proved useful. The cylindrical part of a kettle of this type is tall and narrow. Smaller kettles were occasionally equipped with “crutchers” in the form of perforated plates that could be moved rhythmically up and down through the liquid soap by means of a rod and crankshaft assembly. Stirrers and crutchers served only to intensify the

Figure 4. Generalized flow diagram for the production of soap base

mixing effect. Live steam was introduced here also to induce boiling. Boiling in open kettles is effective for the saponification of both neutral oils and fatty acids. The size of the charge varies considerably, ranging from 500 kg to more than 20 t. Large boiling kettles may have a volume $\geq 100\ m^3$.

4.2.2. Continuous Saponification Processes

Boiling in an open kettle is an elaborate process, and one that is not easy to carry out. The quality and uniformness of the brew is largely a function of the care, manual skill, and practical experience of the soap-maker. This situation was

Figure 5. Flow diagram for kettle saponification [7]

recognized by experts decades ago. After World War II, closed continuous systems increasingly displaced conventional boiling processes, and highly developed process engineering and modern measuring and control technology have now completely changed the face of the soap industry. Nevertheless, replacement of the old soap kettles occurred only gradually, as industry apparently found it difficult to part with the traditional soap-maker's most important piece of equipment. Continuous production lines for processing soap bases into the usual cakes have been standard equipment in soap factories for many decades, though open boiling pans are still seen occasionally. A schematic representation of a Weber & Seeländer type DVN kettle saponification system is shown in Figure 6. It is impossible to describe in this article all the processes (roughly ten in number) available for continuous saponification, and the selection that appears is not meant to imply any value judgment. Every process offers advantages and disadvantages with respect to both soap production and environmental compatibility.

De Laval Process. The De Laval Centripure process illustrated in Figure 7 is an important continuous saponification method that involves centrifuges. Saponification itself is accomplished in a saponification column that functions as a loop reactor. Fat and caustic soda are fed into a circulating stream of liquid soap. To control the pressure, the liquid soap is withdrawn at the top of the column in an amount equal to that of newly formed soap, with fresh brine solution having previously been introduced. The principle of the loop reactor is illustrated in Figure 8. The overall system (Fig. 7) is controlled via the viscosity by measuring the pressure differentials between the suction and delivery sides of the circulating pumps (g). This surprisingly sensitive approach to constant composi-

tion (C – C) control relies on the fact that the viscosity of a soap solution depends on the electrolyte concentration. Soap is very viscous at low electrolyte concentrations, but the viscosity decreases with increasing amounts of electrolyte, passes through a minimum, and then increases again. Changes in viscosity are detected as pressure differences by a differential pressure-sensing instrument, which in turn controls the lye dosing pump. In this manner, alkali concentrations can be adjusted with an accuracy of 0.01 %.

Figure 6. Kettle saponification (Weber & Seeländer, Type DVN)
a) Drum discharge facility; b) Pumps; c) Storage vessels; d) Dissolving vessel; e) Adjusting vessels; f)Dosing vessels; g) Boiling kettles; h) Lye vessels; i) Soap receiving vessel

The saponification column is suitable for both neutral oil and fatty acid saponification. Use of ca. 50 % caustic soda for saponification delivers soap with a 73 % fatty acid content to two centrifugal extractors (c) connected in series, where glycerol is washed out and curd soap is separated. In the first washing stage, lye from the second stage is added to the concentrated soap, which withdraws sufficient water from the wash lye to yield a 63 % curd soap. The lye flow from the first washing stage is diverted to glycerol recovery. In the second stage of extraction the curd soap is washed with fresh electrolyte solution together with nigre from the separators of the fitting stage (e). As noted previously, lye from the second stage flows back to the first extraction stage, which means that soap and electrolyte solution move counter to each other. The fitting step takes place in a second column (d) that receives the curd soap flow from the second wash stage. Curd and nigre are isolated in the subsequent separators (e). Separated nigre is returned together with fresh electrolyte solution to the second wash stage, while the curd is transferred to a drying facility. Similar to kettle saponification, the De Laval process usually produces a 63 % soap base. (All reported soap concentrations refer to the fatty acid content.) However, if the charge consists of fatty acids, the elaborate centrifugal steps become unnecessary and the process can be controlled in such a way (at 135 °C and a pressure of 3.5 bar) that a high-concentration 73 – 74 % soap is formed directly. The drying of such a soap is correspondingly less energy-intensive (see Section 4.3).

Figure 7. Schematic representation of the De Laval Centripure process

Meccaniche Moderne Process. The heart of this process (Fig. 9) is a four-compartment autoclave (a) in which the main saponification reaction occurs at ca. 120 °C and 2 bar. The resulting soap is recycled once and then led into a mixer – cooler (c), which also consists of four compartments, each with an axially arranged

mixer. Here the saponification is completed. The first two compartments of the mixer – cooler are cooled with water, reducing the temperature of the reaction mixture to 90 °C. This decreases the solubility of the soap in the lye; two phases form (soap and lye), which are subsequently separated in a gravity separator. The process is used for the saponification of both fats and oils [8].

Ballestra Continuous Process for the Saponification of Fatty Acid Methyl Esters. This process is based on four steps:

1) Pretreatment of oils and fats
2) Production of fatty acid methyl esters
3) Saponification of the esters
4) Glycerol recovery

Further details and a schematic representation are provided in [9].

Konti Saponification, (Weber & Seeländer, Type KVN). The continuous Sela saponification process for preparing household or toilet soap from neutral fats or neutral oils is illustrated schematically in Figure 10.

The process begins in levelling vessels (a) that are charged from raw material storage tanks, as well as levelling in separate vessels for recycled, glycerol-enriched lye. Control of the four process steps is accomplished through multiple-head dosing pumps (b), (c), and (h), where each dosing component can be individually controlled.

Saponification is carried out at 110 – 120 °C by introducing fats and caustic soda into a saponification cycle consisting of saponification reactor 1 (d), a feed pump (e), and a homogenizer (f). The reactor and circulating system are heated to facilitate start-up and shut-down. The reactor can also be cooled to dissipate heat generated during the saponification. Saponified product is fed into reactor 2 (g) for cooling, where it can also be neutralized with fatty acid. Like stage 1, this stage also consists of a reaction vessel with its associated feed pump and circulation system. The soap leaves this stage at ca. 90 °C. As a rule, saponification is adequately controlled by manual sampling for adjustment of the alkali content.

In the washing stage, soap and glycerol are separated by liquid – liquid countercurrent extraction. Washed soap leaves the extractor (i) from the top, after which it is fed into the fitting stage. A glycerol – water mixture is withdrawn at the bottom of the extractor and fed into the lye levelling vessel via a float valve. From here it is recycled to the saponification stage by way of two dosing pumps. Enriched glycerol – water is simultaneously withdrawn for evaporation by means of a third pump.

In the next stage the curd soap is fitted in a fitting reactor by the addition of fitting solution (NaOH). Like the cooling stage, this stage also consists of a reaction vessel (j) with a feed pump and a circulating system. The two phases, soap curd and nigre, are heated to ca. 95 °C, leaving the reactor as a mixture.

Figure 10. Continuous saponification system (Weber & Seeländer, Type KVN)
a) Level-control dosing vessels; b) Dosing pump with five dosing heads; c) Dosing pump with a single dosing head; d) Saponification reactor (reactor 1); e) Feed pumps; f) Homogenizer; g) Cooling reactor (reactor 2); h) Dosing pump with two dosing heads; i) Extractor; j) Fitting reactor; k) Leveling vessel; l) Pump; m) Centrifugal separator [alternative: n) Settling vessel]

Continuous separation of the two phases is achieved by means of a centrifuge (m), with nigre and lye being recycled to the process. Alternatively, phase separation can be accomplished in heated boiling kettles (n), each kettle being left to settle undisturbed for ca. 24 h. With two such kettles, heating and 24-h settling can be alternated, providing another approach to continuous operation with nigre and lye recycling.

For details concerning the widely practiced Mazzoni soap-making process, see [10].

4.2.3. Batch Processes

Saponiflex Process (Eirich). This modern soap-making process, developed by Eirich, permits fully automatic operation. Saponification, drying, cooling, and vigorous incorporation of all the required additives for a finished soap take place within the confines of the Eirich reaction mixer. The process, represented schematically in Figure 11 [11], is applicable to finished soap production from fats and oils, fatty acids, fatty acid methyl esters, and even syndets (see Chap. 6).

The principal raw materials–in this case fatty acids–are stocked in heated tanks (a), which maintain the components in their liquid state. Tank (b) is a storage tank for 50 % sodium hydroxide or a dissolving tank equipped with a stirrer for flakes of caustic soda. Other starting materials include coloring agents and miscellaneous additives [tanks (c)]. A computerized weighing system is employed, with dosing effected by triggering devices (d). Fatty acids are introduced first, followed by sodium hydroxide solution. Other additives are incorporated dur-

ing the reaction phase. The temperature in the mixing reactor (e) rises to >100 °C. Cooling is initiated at the appropriate time by application of a vacuum. Evaporating water condenses in a multitube heat exchanger (f) and returns to the mixture. In a subsequent drying phase, the appropriate amount of condensate is collected in a scale (h) and removed. No supplemental energy is required for saponification or drying.

Temperature-sensitive components (e.g., perfume oils) are added after the cooling and drying processes.

The Eirich mixing reactor (Fig. 12) consists of a rotating vessel for mixing the charge, a stationary combination device (baffle and bottom – wall scraper), and a rapidly rotating stirrer. The use of a rotating vessel together with stationary components causes the material to be circulated continuously and mixed both vertically and horizontally. The rotating mixer is responsible for ensuring intensive preparation and dispersal of any agglomerates, as well as bringing the various components into contact with one another. Sodium hydroxide solution is mixed very quickly with the saponifiable components. The entire process is monitored and controlled automatically via a programmable control system that includes automatic recording, balancing, and alarm functions.

Numerous other batch processes exist as well, including semiboiled saponification systems from Weber & Seeländer (types DHA and DHT).

4.3. Drying

Fitting results in a liquid base soap with a fatty acid content of 62 – 63 %, but material with a 78 – 80 % fatty acid content is required for the manufacture of high-quality soap. The fatty acid content can be increased by drying. Household and toilet soaps are dried to water contents of ca. 24 % and 12 %, respectively. At the same time, the soap must be cooled to 20 – 30 °C to provide the strength necessary for further processing. The development after World War II by the Italian firm G. Mazzoni S.P.A. of vacuum spray systems for drying base soaps led

ultimately–despite initial start-up problems–to a technical revolution in the soap industry, and vacuum drying remains the drying process of choice. Evaporated water and soap are expanded under a pressure of 20 – 40 mbar, which simultaneously cools the soap to 20 – 30 °C. Water vapor is removed from the vacuum system by condensation.

Figure 12. Cutaway view of the Eirich mixing reactor

Vacuum Dryers. Figure 13 illustrates the design of a vacuum drying facility (Weber & Seeländer) [12]. Soap base from a saponifier is pumped through filters (a) into a feed tank (c) equipped with level control. Soap is then fed continuously into the dryer at a rate established by a dosing pump (d). The first stage is a heat exchanger (e) designed for a steam pressure of 9 bar absolute and a soap base inlet temperature of 80 °C. The soap is cooled in an evacuated spray chamber (f) to the temperature at which water boils at that pressure, after which it is sprayed onto a rotating cone (Fig. 14). The cone is firmly supported from outside the zone that comes into contact with the soap; the inner surface, which is in contact with the soap, is very accurately machined. This arrangement facilitates safe and virtually maintenance-free removal of the dried soap by means of a flexible scraper. Vacuum-tight soap discharge from the vacuum chamber is accomplished with a worm-type extruder (g). In the case of household soap, the dryer discharge normally takes the form of soap strands that emerge, for example, from a duplex vacuum extruder. Water evaporated during the drying process is passed through centrifugal dust collectors (h) to remove accompanying soap dust, after which it is condensed in a vent- or suface-type condenser (k). High-temperature cooling water systems require vapor compression with a steam-jet compressor (j) prior to condensation in order to achieve an equilibrium water-vapor pressure in the condenser

Figure 13. Schematic repesentation of a Weber & Seeländer vaccum drying and cooling system

corresponding to the temperature of the cooling water. Withdrawal of noncondensable gases and air that may have leaked in is achieved either with a steam-jet device or mechanical pumps. A similar system from the Italian firm Impianti macchinesaporne affine S.R.L. (i.m.s.a.) is illustrated in Figure 15 [13].

Figure 14. Rotating-cone spray dryer (Weber & Seeländer)

Alternatives to vacuum dryers include atmospheric-pressure dryers and cooling rolling mills, or vacuum dryers preceded by pressure release devices. The latter type of combination dryer provides fatty acid concentrations >68 % with simultaneous vacuum cooling, and it entails a minimal amount of cooling water for vapor condensation. In this case, the vacuum system serves only to effect cooling; the heat of condensation is essentially equivalent to heat removed in cooling the soap, so the demand for cooling water is correspondingly small. Water evaporation in this case occurs primarily in the prior atmospheric stage.

4.4. Storage

Soap flakes or noodles from the drying system are generally stored in bins before further processing. If the soap were to be processed immediately, soft bars would result depending on the soap-making oils and fats and the extent of drying, and these would tend to stick to the die of the soap press or cause problems in the packing machines.

Storing soap noodles in silos poses no problems if properly done. However, moisture diffusing outward from the interior of the ribbons cannot be absorbed at the surface, and may settle on the ribbon surfaces producing an effect known as "sweating". Wooden bins are ideally suited to the storage of soap noodles and flakes, because the porosity of wood permits moisture to escape and evaporate on the outside of the bin.

The most convenient shape for a soap silo is a box-like room with a cone to facilitate discharge of the soap to the processing machines. Belts, screws, and elevators are generally used for transport.

4.5. The Finishing of Soap Base

The processes described above give rise to a granular, pourable soap base that serves as the starting material for producing finished soap. This material has a water content of ca. 14 %, and it contains ca. 0.5 % NaCl as well as a maximum of 0.05 % free alkali, which provides some protection against rancidity. In the case of kettle saponification, the soap base still contains 0.5 – 1 % glycerol. The material has a white to yellowish color and a neutral odor. The following finishing steps are required to produce a final product:

1) Incorporation of additives for optimizing the application characteristics, producing soap with special properties, and fragrance adjustment
2) Plodding
3) Cutting into unfinished pieces
4) Forming
5) Packaging

A schematic representation of the finishing operations for producing bars of soap is provided in Figure 16.

Two methods are available for mixing and homogenizing toilet soaps:

1) Trough mixing, followed by "pilling" on a set of rolling mills. Modern equipment for this purpose has been in use for many decades. Three- and four-roll mills are most common.

Figure 15. Schematic representation of a drying and cooling system (i.m.s.a.)

a) Soap granulate silo; b) Storage vessel with dosing pump for color, fragrance, and additives; c) Mixer; d) Soap plodder and log extruder; e) Log cutter; f) Forming press; g) Automatic bar packer; h) Automatic cartoning unit; i) Palleting

2) Mixing and homogenization in a screw device. This process reached technical maturity only after World War II, with pioneering work again carried out by the Italian company Mazzoni.

Unlike trough mixers which process batches of soap, screw mixers (often called automatic refining machines) operate continuously. Mixing and plodding are usually accomplished in separate devices, although some machines combine the two functions.

Soap base is fed into a discontinuous mixing machine via (automatic) scales or calibrated star wheels. The appropriate small amounts of additives can be weighed by hand and added selectively to each batch. In a continuous mixing machine, perfume oils, skin-protecting agents, coloring matter, and other additives are combined as a slurry that is introduced continuously with a dosing pump.

The pelletized soap mass is then plodded, generally with a two-stage vacuum extruder. A vacuum worm extruder for this purpose consists essentially of a series of worm extruders with vacuum chambers located between each pair of worms. In the simplest case, a duplex machine like that shown in Figure 17, the plastic soap mass is precompressed in the first screw extruder (b), where it is also homogenized once again, after which it is converted in the usual way to soap noodles by extrusion through a perforated plate (die) coupled with a rotating cross-shaped cutter (c). The noodles fall into a vacuum chamber where they are lifted by the main screw (d) and extruded under high compression though a die at the head of the extruder (e). What emerges is a compact, bubble-free, glossy strand. Any breakdown in the vacuum chamber interferes with proper degassing, which can lead to bubbles in the soap strand that crack during use.

The strand is subsequently cut into unfinished pieces, which must closely approximate the desired dimensions for the finished soap bars. Machines equipped with cutting chains are now standard (e.g., machines similar to those from i.m.s.a., as shown in Fig. 18).

The unfinished pieces are stamped into their final shape in soap presses. High-speed presses

are normally used on high-volume production lines. The form of the stamp is established by designers, taking into account legal considerations such as the minimum net weight for a soap bar.

Figure 17. Duplex single-screw extruder (Weber & Seeländer)
A) Side view; B) Top view a) Soap hopper; b) Ribbon extruder; c) Ribbon cutter; d) Primary vacuum extruder; e) Log discharge

The finished bars are packaged and then placed in storage. The packaging machine [15] is usually located directly behind the press, and is adjusted to conform to its working cycle. Here the finished product is wrapped in packaging materials chosen to provide suitable protection during transport. Automatic cartoning machines are used to pack the product into boxes, which are then loaded onto pallets.

Occasionally it becomes necessary to subject a soap to interim storage before packaging to permit secondary hardening to take place.

5. Characteristic Features of the Most Common Types of Soap

5.1. Toilet Soaps

Toilet soaps are used for body cleansing and personal hygiene. Based on turnover and distribution they represent the most important type of soap. Toilet soaps are sodium soaps made from high-grade fats, such as coconut oil, beef tallow, palm oil, and olive oil, with a fatty acid content of ca. 80 %. Good foaming properties require that the starting materials contain 20 – 50 % coconut oil. Toilet soaps are slightly superfatted, in that they contain 1 – 10 % free fatty acids, fatty alcohols, glycerol, lanolin, petrolatum, cocoa butter, almond oil, wheat germ oil, or fatty acid ethanolamides [16]. These superfatting agents ensure the refatting of freshly cleansed skin. Cosmetic dyes are introduced for coloring purposes at a level of $\leq$0.1 % in accordance with government regulations. Patented processes permit the preparation of marbled or striped soaps. Added brilliance is achieved with titanium dioxide. Complex mixtures of natural and synthetic perfume oils are also employed (0.5 – 5 %, with a trend toward more). Special effects are achieved with substances such as honey, camomile extracts, milk powder, or abrasives. Antioxidants and optical brighteners are also used occasionally. Antioxidants (e.g., butylated hydroxytoluene) and complexing agents [e.g., ethylenediamine tetraacetic acid (EDTA) and (1-hydroxyethane-1,1-diphosphonic acid [*2809-21-4*] (HEDP)] prevent a soap from becoming rancid. The role of the complexing agents is to bind catalytically with active heavy metals.

Soap bars are subject to repeated contamination with bacteria from water or washed from the skin [17], so they have sometimes been regarded as "hygienically questionable." Bacterial survival in toilet soaps, especially those containing special additives like proteins, can be countered by addition of a preservative. It has been found in practice, however, that preservation of this type is usually required only in exceptional cases.

5.2. Other Soap Products

Luxury Soaps. For soaps in this category the typical toilet soap charge is supplemented with a high proportion ($\leq$ ca. 5 %) of perfume oils.

Deodorant soaps contain an active ingredient such as 3,4,4′-trichlorocarbanilide (trichlocarban) to inhibit the growth of skin bacteria responsible for the formation of odor-causing

substances from perspiration (→ Skin Cosmetics, Chap. 8.).

Figure 18. Example of a soap-cutting machine (i.m.s.a. Model TE)

Skin-protecting soaps are perfumed only slightly and contain refatting substances as well as additives that not only reduce the scouring effect of the soap, but also positively influence the state of the skin after washing (e.g., proteins, milk components).

Cream Soaps. Cream toilet soaps are exceptionally rich in refatting substances. The fat charge frequently contains a high proportion of coconut oil.

Transparent soaps are partially transparent, because special substances (e.g., glycerol, ethanol, sugar) have been added to prevent crystallization.

Abrasive soaps contain abrasive substances (e.g., quartz, sand, almond bran) to help remove stubborn dirt.

Floating Soaps. These soaps have a density <1 g/cm^3 and therefore float on water. They are made by working air into the soap during production, or by creating an air pocket within the soap bar.

Liquid soaps are potassium soaps with a fatty acid content of ca. 15 – 20 %. The fat charge includes coconut oil in addition to other vegetable oils. Liquid soaps are preferred for use in soap dispensers, because their discharge rate is easily controlled. A typical formulation for a liquid soap (in wt %) is as follows [18]:

Potassium salt of coconut oil fatty acids	ca. 15
Potassium salt of oleic acid	3
Glycerol	5
Refatting agents	5
Pearly-luster agents	2
Special additives, complexing agents, lime soap dispersing agents, perfume oils and dyes, water	balance

Baby Soaps. These toilet soaps are well superfatted and only slightly perfumed, if at all. They also contain special additives such as camomile constituents.

Shaving soaps and creams are mixtures of sodium and potassium soaps to which 5 – 10 % of a moisturizer (glycerol) is added. Shaving soaps command a much smaller share of the market than shaving creams and especially shaving foams (→ Hair Preparations, Chap. 8.3.). The following is a typical formulation (in wt %) for a shaving soap [19]:

Fatty acids, alkali salts (with 20 – 25 % originating from coconut oil or palm kernel oil)	ca. 80
Glycerol	5 – 10
Water	8 – 10
Perfume oils	1.5 – 2.5

Hard Soaps. These are sodium soaps made from fats and oils similar to those used for toilet soaps. Their fatty acid content is 60 – 65 %. Hard soaps are used mainly for washing the hands and occasionally for washing clothes.

Soft Soaps. This is a collective name for soaps with a paste-like consistency. They share the characteristic of having been saponified with potassium hydroxide. A distinction can be made between smooth, transparent, and granular products. The colors range from white to yellow, brown, or green. Soybean oil, olive oil, and

peanut oil can all be used for the fat charge. The fatty acid content is ca. 40 %. These soaps are intended for floor cleaning and similar tasks.

Soap flakes and soap needles are highly dried sodium soaps with a fatty acid content of ca. 85 %. They are used primarily for industrial purposes, especially in laundries and for textile finishing.

Table 3. Basic formulation for the manufacture of syndet bars [21]

Component	Content, %
Fatty alkyl sulfates ∗	30 – 60
Builders/plasticizers: mono-, di-, and triglycerides, paraffins, microwaxes, fatty alcohols	30 – 50
Fillers: starch, talcum, zinc oxide, titanium oxide	0 – 15
Refatting/superfatting agents: lecithins, lanolin, oils, alkanolamides	1 – 7
Active ingredients: D-panthenol, vitamin E, amino acids, disinfectants	1 – 3
Water and moisturizers: lactates, amino acids, sorbitol, glycerol	1 – 5
Coloring agents	0 – trace
Perfumes	0 – 1

∗ Alternative surfactants: (1) fatty alkyl sulfosuccinates, 10 – 35 %, and fatty alkyl sulfates, 10 – 40; (2) fatty acid isethionates, 10 – 40 %, and fatty alkyl sulfates, 10 – 40 %; (3) fatty acid isethionates, 30 – 50 %, and fatty alkyl sulfosuccinates, 0 – 20 %; (4) potassium salts of fatty alkyl sulfonates, ca. 70 %.

6. Syndets

The term "syndet" is derived from *syn*thetic *det*ergents (→ Laundry Detergents), and refers to soap-free products for skin-care and skin-cleansing applications. In the broadest sense, bath and shower preparations also belong to this group (→ Skin Cosmetics, Chap. 7.). However, the term syndet is usually restricted to cosmetic products in bar form [20].

Soaps and syndets share one common characteristic: they contain surfactants as their main components. Soaps are salts of strong bases and weak acids, so they always give an alkaline reaction in aqueous solution, and lose their surfactant properties under neutral or acidic conditions. This is not true with syndets, which can be "pH controlled". Soaps react with hardness-causing ions, especially calcium ions, to form slightly soluble, wash-inactive salts called lime soaps (→ Metallic Soaps) with a consequent loss of surfactant properties. Syndets do not form insoluble lime soaps. Their cleansing power can be adjusted for a particular application by appropriate choice of the surfactants, permitting skin cleansing under neutral to acidic conditions. Both solid (bar) and liquid formulations are available.

Constituents. Solid syndets contain the following principal ingredients [21]:

1) Wash-active substances
2) Builders/plasticizers
3) Fillers
4) Perfume oils/coloring agents

Basic formulations for the preparation of solid syndets are provided in Table 3.

Liquid products (Table 4) differ by the inclusion of such additional substances as thickening agents, refatting agents, or substances to increase compatibility, active ingredients, preservatives, and antioxidants.

Table 4. Basic formulation for the manufacture of liquid syndets [21]

Component	Content, %
Ether sulfates, organic neutralized (56 %) ∗	30 – 40
Protein fatty acid condensates ∗	0 – 5
Betaines ∗	0 – 5
Protein hydrolyzates	0 – 5
Thickening agents	1 – 8
Pearly-luster agents	0 – 5
Refatting agents	1 – 7
Active ingredients	1 – 5
Coloring agents	0 – trace
Perfume oils	0 – 1
Preservatives, antioxidants	0.05 (0) – 1

∗ Alternative formulations with respect to the first three components (surfactants): (1) betaines, 10 – 40 %, and fatty alcohol ether sulfosuccinates, 10 – 30 %; (2) betaines, 10 –40 %, and protein fatty-acid condensates, 5 – 15 %; (3) protein fatty-acid condensates, 20 – 50 %, and olefin sulfonates, 0 – 20 %; (4) fatty alcohol ether sulfates, 25 – 45 %, and ether carboxylates, 5 – 15 %; (5) fatty alcohol ether sulfosuccinates, 20 – 35 %, and fatty alcohol sulfoacetates, 10-15 %.

Production. Solid syndets are made on standard soap production lines. Liquid preparations can be mixed in vessels equipped with high-speed rapid stirrers, anchor stirrers, or similar devices, starting with raw materials that are either liquid at room temperature or liquified by heating.

Outlook. In the future, syndets are expected to press forward vigorously into the field of skin care because, unlike soaps, they lend themselves to a widely diversified range of products with respect to chemical composition, cleansing power, pH, and skin-care properties. Details regarding skin compatibility are best sought in the technical literature [22].

7. Environmental Protection

A simplified ecological balance for soap is presented in Figure 19. Used soap collects in wastewater, where it is degraded biologically either in the water itself under aerobic conditions or anaerobically in waste-treatment sludge. Unlike other anionic surfactants, the degradability of a soap cannot be evaluated by measuring primary degradation, because soaps show no methylene blue activity. For this reason, soap levels must be quantified by other means (e.g., gas chromatography) after various periods of degradation [23].

In 1991, The Netherlands' Organization for Applied Scientific Research (TNO) Institute of Environmental Sciences published a report on the biodegradability of soaps from fatty acids with different carbon chain lengths [24]. This report concluded that even after short time periods a high level of primary bacteriological degradation is achieved in all cases. The requirement for a biodegradation of >60 % (e.g., in the closed-bottle test) is readily met within short test periods, indicating that soaps are characterized by excellent degradability. All the evidence points to rapid degradation in waste-treatment plants as well. Both short- and long-chain soaps are degraded completely under aerobic conditions.

For information on the effects of syndet preparations on the human environment see [25].

8. Quality Control and Analysis

Paragraph 4 of the German Food and Commodities Law describes cosmetic articles as "substances and preparations made from materials intended for human use, either externally or in the oral cavity, for the purpose of cleansing, care, influencing appearance or body odor, or imparting odoriferous sensations", in contrast to substances whose primary purpose is to "alleviate or eliminate disease, injury, physical damage, or pathological complaints". Therefore, based on this definition, ordinary soaps and syndets must be regarded in Germany as cosmetic agents. This generalization does not apply to medicinal soaps, which are not discussed here. It is mandatory that soaps and syndets be free of potential hazards to human health. In Germany they are also subject to the requirements of the statute on cosmetics [26], which regulates the nature of permissible ingredients. Coloring agents and allowed preservatives are covered by the "Blue List" [27].

A typical toilet soap granulate should be consistent with the following analytical specifications immediately after production:

Bound fatty acids	79.0 ± 1 %
Free NaOH	0.05 ± 0.02 %
NaCl	0.4 ± 0.1 %
Loss on drying	12.5 ± 1 %
Complexing agent	positive test

Product appearance and odor are also tested. Recognized analytical procedures include the uniform methods for testing fats, fat products, and related substances issued by the German Society for Fat Science (Deutsche Gesellschaft für Fettwissenschaft e. V.), Münster/Westfalen. Analytical characteristics for a typical bar of toilet soap include:

Appearance:	color corresponding to a standard sample
Odor:	characteristic, identical to that of a standard sample
Bound fatty acids:	78.5 ± 1.5 % (based on a saponification number of 219 ± 2)
Free alkali:	0.04 ± 0.02 %
Petroleum ether extract:	1.5 ± 0.2 %
Smoothness:	remains smooth during washing with luke-warm water
Cracking:	no cracking in a wet-crack test

Information on quality control for syndet-containing cleansing agents is available from [28]. In this case the most important quality characteristics are convenience, foam development, foam quality, swelling behavior, economic factors, tendency to crack, and compatibility with the skin.

Figure 19. Simplified ecological balance for soap

9. Economic Aspects

With a production of 8.9×10^6 t in 1990, soaps still ranked first in worldwide statistics for surfactants [29]. They account for 56 % of total surfactant production, primarily because soap is very economical and can be produced inexpensively. The use of soap as a builder in liquid detergents has recently become somewhat more important in the Western European market, although its use as an antifoaming agent continues to decrease (→ Laundry Detergents, Chap. 3.4.3.). However, soap is not a suitable alternative to the usual surfactant-based, heavy-duty detergents. Soap is used to wash clothes in less than 1 % of German households.

On the whole, soap production has remained relatively stable in the past few years. The 1990 worldwide rate of increase (2.2 %) slightly exceeds the increase in population (1.8 %). Toilet soaps, with a production volume of 2.7×10^6 t/a, display a significantly lower growth rate (1 %). The consumption of soap in 1990 was 0.68×10^6 t in Western Europe, 0.70×10^6 t in the United States, and 0.19×10^6 t in Japan, giving a total of 1.57×10^6 t. Figure 20 shows the ten most important soap-producing countries (1990). Current per capita soap consumption in Western Europe is about 2.1 kg, and the world average is 0.5 kg.

The syndet market share is largest in the United States. In Western Europe, pH-regulated soap bars and liquid syndets in the form of washing lotions are steadily gaining importance.

Figure 20. Overview of production data for the ten leading soap-producing countries [28]

10. Toxicology

Considered from the point of view of a cleansing and cosmetic agent, soap comes in contact only with the exterior of the body. Experience indicates that daily use of the product is unlikely to be a source of problems. From a toxicological and dermatological perspective, excessive application or prolonged contact of the skin with soap solutions can result in protein denaturing and the release of amino acids. The emulsifying action of a soap is responsible, on the one hand, for the

desired cleansing action, but it can also lead to the removal of natural oils from the horny layer of the skin; overtaxing the skin's regenerative capacity can have deleterious effects on its barrier functions. Excessive application may result in increased swelling and barrier-function disturbances that in turn lead to eczema-like manifestations. Allergic reactions to soap products have also been observed, but specific allergies to soap itself are rare. Individual reports in the literature point to perfume oil additives as the most common cause of problems. Irritation may also accompany the action of high concentrations of soap powder or soap solution on eye tissue. Injection of soap solutions can cause necrosis and hemolysis. Depending on the dose, oral ingestion of soap (typically by small children) may lead to local irritation of the mucous membranes, nausea, vomiting, and foam buildup, which can in turn induce aspirative pneumonia. Gastrointestinal disorders such as flatulence and diarrhea have also been reported. Generally speaking, however, the quantity of soap ingested is so small that risks of serious or prolonged damage to the health are insignificant.

1. Introduction

In 1811, DAVY and GAY-LUSSAC reported: "If sodium is heated in gaseous ammonia, an olive-green compound is formed. Ammonia is absorbed, and an amount of hydrogen is evolved equal to the amount that would be evolved if the same amount of sodium were added to water" [1].

The reaction

$$2\,NH_3 + 2\,Na \rightarrow 2\,NaNH_2 + H_2$$

proceeds quantitatively according to BEILSTEIN and GEUTHER when oxygen-free, dry ammonia is passed over heated sodium for 6 – 7 h. As the reaction proceeds, greenish blue droplets form on the metal surface [1].

In 1863, T. WEYL discovered that alkali metals dissolve in liquid ammonia to give colored solutions. Since then, these solutions [2], with their unusual properties, have been intensively investigated [3].

This is also true of sodium amide [4–6], a compound whose industrial exploitation is described in detail in [7], [8].

2. Properties

2.1. Physical Properties of a Solution of Sodium in Liquid Ammonia

Sodium dissolves in liquid ammonia without evolution of hydrogen to give a deep indigo blue color [9]. The characteristic properties of this solution are its color, its electrical conductivity, and its magnetic susceptibility [2]. The conductivity of the dilute solution is about an order of magnitude higher than that of completely dissociated salts in water. With increasing concentration, the conductivity first decreases, reaching a minimum at 0.04 mol/L, and then increases to values typical of liquid metals. Dilute solutions are paramagnetic, with a susceptibility corresponding to one free electron per metal atom. The susceptibility decreases with increasing concentration. The solution is diamagnetic in the region of the conductivity minimum, and then becomes slightly paramagnetic at higher concentrations. The changes in properties with concentration can be explained on the basis of the equilibrium reaction between liquid ammonia and dissolved sodium [2]:

$$Na_{(dissolved)} \rightleftharpoons Na^{+}_{(dissolved)} + e^{-}_{(dissolved)}$$

Gibson and Argo first coined the expression "solvated electrons" for the "state of excess electrons" in liquid ammonia [3]. It has been suggested that, in liquid ammonia, alkali metal anions, e.g., sodium anions, could exist with a centrosymmetric structure with both the valence electrons in an *s* orbital [3], [10].

On the basis of the fact that the solution $Na-NH_{3(liq.)}$ has a much lower density than liquid ammonia and hence a higher volume than would be expected from the sum of the volumes of the metal and the solvent, concepts of the structure of such solutions have been developed

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_267

[2], [3], [11], [12]. The increase in the apparent molar volume must be due to the unusual state of solution of the electrons, since volume increases of this order are not observed for solutions of other substances. On the contrary, when ionic substances are dissolved, there is a considerable volume decrease due to electrostriction [13].

The increase in equivalent conductivity by several orders of magnitude when the concentration of alkali metals (e.g., sodium) in liquid ammonia increases to >0.5 mol/L is associated with a transition from a "nonmetallic" to a "metallic" state. In the concentration range where the conductivity is highest, a miscibility gap is observed at low temperature. The $Na-NH_3$ solution splits into a dilute "nonmetallic" phase and a concentrated "metallic" phase, both in equilibrium with sodium [14]. The denser phase is blue and has a lower metal concentration than the less dense bronze-colored phase [15]. The miscibility gap is illustrated in Figure 1 [13], [15].

Figure 1. Excerpt from the $Na-NH_3$ phase diagram showing the eutectic and the miscibility gap, which is displaced to lower temperature and higher concentration on application of pressure

The observed physical and chemical properties of solutions of alkali metals in liquid ammonia have not yet been explained by a single model [11], [13], [16].

2.2. Physical Properties of Sodium Amide [17]

The solubility of alkali metal amides, including sodium amide, in liquid ammonia is low. Some figures for the solubility of sodium amide in liquid ammonia (in g $NaNH_2$/100 g NH_3) are given below [18]:

T, °C	−20	−10	0	+10	+20
Solubility	0.114	0.130	0.140	0.149	0.163

The solubilities of predominantly ionic solids increase with increasing dielectric constant of the solvent [6]. Figure 2 shows the values of the dielectric constants of ammonia and water as a function of temperature. Water is the best-known protic solvent. The dielectric constants of ammonia are much lower than those of water. Hence, ammonia is a less effective solvent for inorganic compounds [6].

Figure 2. Dielectric constant ε as a function of temperature for ammonia and water [6]

Since sodium amide does not form a solid ammoniate, single crystals of $NaNH_2$ can be obtained from liquid NH_3 at room temperature. The properties and structure of $NaNH_2$ have been extensively investigated [6].

Sodium amide, $NaNH_2$, M_r 39.02, *mp* 208 °C, $\varrho_4^{25} = 1.39$ g/cm^3, enthalpy of formation at 25 °C $\Delta H^0 = -113.8 \pm 2$ kJ/mol, forms colorless, strongly birefringent, anisotropic crystals with a rhombic face-centered crystal structure, and a lattice energy of 774 kJ/mol. The lattice consists of Na^+ and NH_2^- ions [19], [20].

A 0.01 mol/L solution of $NaNH_2$ at − 33.5 °C is 3.8 % dissociated into Na^+ and NH_2^- ($K_{\text{dissoc.}} \approx 2.65 \times 10^{-5}$ [17]).

2.3. Chemical Properties

Solutions of sodium in liquid ammonia are versatile reducing agents and can also be used for elimination reactions. Some examples of these reactions are [13], [21]:

1) Redox reactions
2) Reduction of alkynes
3) Reduction of aromatic systems (Birch reduction)
4) Dehalogenation and decyanidation reactions

Sodium amide has a wide range of uses in chemistry. Comprehensive reviews of its reactions are available in [2], [5], [6], [19], and [21–23]. A few examples of these are:

1) Deprotonation of organic compounds
2) Dehalogenation
3) Reactions with primary and secondary amines
4) Initiation of the anionic polymerization of ionic chains
5) Amination of pyridine (Chichibabin reaction)
6) Cleavage of ketones (Haller – Bauer reaction)

2.3.1. Chemical Properties of Na – NH_3 Solution

Solutions of sodium in liquid ammonia are metastable at equilibrium pressure and room temperature, and decompose gradually, forming sodium amide [6].

Redox Reactions. Solutions of alkali metal salts in ammonia develop a blue color at the cathode on electrolysis due to the formation of solvated electrons. The thermodynamically favored formation of hydrogen at the cathode is completely prevented by a high voltage excess. The reaction inhibition that leads to the hydrogen voltage excess is possibly caused by the low rate of reaction of the solvated electrons with ammonia [13].

Thermodynamic considerations, including the overvoltage observed in liquid ammonia at the hydrogen and nitrogen electrodes, have been invoked to explain [2], [24] why it is possible to work in liquid ammonia both with powerful reducing agents, and with powerful oxidizing agents. Examples of these reactions are given in [1], [2]. The solvated electrons, which have a large negative redox potential, can react with many dissolved substances [13]. Thus, with the exception of the ions of the alkali metals, alkaline-earth metals, and divalent rare earth metals, all metal cations are reduced by solvated electrons.

Anions with completely filled electron shells, such as F^-, Cl^-, Br^-, I^-, CN^-, CNO^-, CNS^-, N_3^-, and OH^-, do not react with solvated electrons. Also, the following nonmetallic oxo-anions, which are in their highest oxidation state, are inert toward solvated electrons: $B_4O_7^{2-}$, CO_3^{2-}, HCO_3^-, ClO_4^-, HPO_4^{2-}, PO_4^{3-}, SO_4^{2-}. However, high reactivity is shown by the metal oxo-anions such as MnO_4^- and $Cr_2O_7^{2-}$, and by all the oxo-anions of nitrogen, bromine, and chlorine (except ClO_4^-) [13].

An example of the reduction of transition metal complexes to unusually low oxidation states is provided by the following equation [2]:

$$Fe(CO)_5 + 2\,Na \xrightarrow{NH_3/-33\,°C} Na_2[Fe^{-II}(CO)_4] + CO$$

High-pressure ammonolysis opens up new synthetic possibilities, for example, for some hydroxides, hydrosulfides, and chalcogenides [6].

Reduction of Alkynes. Only internal triple bonds can be reduced by sodium in liquid ammonia. Terminal alkynes are converted to acetylide ions under these conditions:

$$RC{\equiv}CH + e_{\text{diss.}} \rightarrow RC{\equiv}C^- + 1/2\,H_2$$

Isolated double bonds in organic compounds are not reduced, but allenes, conjugated dienes, and aromatic rings are [21].

Reduction of Aromatic Systems (Birch Reduction) [21]. If aromatic rings are reduced by sodium in liquid ammonia, usually in the presence of an alcohol, 1,4-addition of hydrogen results to give a nonconjugated cyclohexadiene in good yield. When substituted benzenes are

reduced, often a single product is formed. Thus, the reduction of *o*-xylene is a good route to 1,2-dimethyl-1,4- cyclohexadiene [25]. Naphthalene can be regioselectively hydrogenated to 1,4-dihydronaphthalene. If an excess of sodium is used, 1,4,5,8-tetrahydronaphthalene is obtained [26]. Reduction of thiophene by sodium in liquid ammonia in the presence of methanol gives 2,3- and 2,5-dihydrothiophene [26].

Dehalogenation and Decyanidation. Instead of the more commonly used zinc and magnesium, $Na-NH_3$ can be used to dehalogenate vicinal dihalides [13], [21].

Sodium in liquid ammonia can also be used to remove the cyanide group from alkyl nitriles. If the nitrile compounds also contain, e.g., trityl, benzyl, phenyl, or tertiary alkyl groups, the reaction with $Na-NH_3$ solution gives high yields. Considerably lower yields are obtained with primary or secondary alkyl groups. It is thought that the solvated electrons in the $Na-NH_3$ system are responsible for the reaction mechanism, which proceeds via free radicals and then carbanions [13], [21].

2.3.2. Chemical Properties of Sodium Amide

Sodium amide is a strong base [19], [27]. The reaction of ammonium salts with metal amides in liquid ammonia proceeds analogously to the neutralization of acids by bases in water, for example

$$NH_4NO_3 + NaNH_2 \rightarrow NaNO_3 + 2\,NH_3$$

Metal amides such as sodium amide behave as bases in the ammonia system, like metal hydroxides in an aqueous system. Hydrolysis corresponds to ammonolysis in ammonia. The proton affinity of ammonia, i.e., the energy released when a proton bonds to an NH_3 molecule, is 875 kJ/mol, which is much greater than the proton affinity of water (762 kJ/mol) [19]. Correspondingly, the proton affinity of NH_2^- is considerably higher than that of OH^-. The proton affinity of OH^- in the gas phase is 1634 kJ/mol, but in water this decreases to 1188 kJ/mol due to hydration of OH^-. Bases A^- whose effective proton affinity in water is >1188 kJ/mol are completely converted to the corresponding acid HA with formation of OH^-. For this reason, NH_2^- cannot be studied by dissolving its salts in water, because OH^- ions are formed quantitatively and the NH_2^- ions are completely protonated to NH_3 [27].

This behavior is known as the "leveling effect" of the solvent. Any base that is strong enough to react with water completely to form OH^- ions is leveled. Thus, OH^- is the strongest base that can exist in water [27]. Therefore, depending on the temperature and the solubility of the reactants and end products, liquid ammonia or inert hydrocarbons can be used as media for reactions with sodium amide [17].

Deprotonation. In liquid ammonia, sodium amide acts as a strong base, like NaOH in water. It deprotonates terminal triple bonds to form strongly nucleophilic acetylide anions [25]:

$$RC{\equiv}C^- + R'X \rightarrow RC{\equiv}C{-}R' + X^-$$

By using a series of reactions, it is possible to build up longer chains from shorter ones, and to prepare *cis*- or *trans*-alkenes

Another example of the basicity of $NaNH_2$ is its reaction with di- and triphenylmethane, which are converted into the corresponding carbanions [25]:

$$(C_6H_5)_2CH_2 \xrightarrow[-NH_3]{NaNH_2} (C_6H_5)_2CH^-Na^+$$

$$(C_6H_5)_3C{-}H + NaNH_2 \overset{-NH_3}{\rightleftharpoons} (C_6H_5)_3C^-Na^+$$

Dehalogenation. Sodium amide can be used to prepare alkynes from geminal or vicinal dihalides [25]:

$$\left.\begin{array}{l} RCX_2CH_3 \\ RCHXCH_2X \\ RCH_2CHX_2 \end{array}\right\} + 2\,NaNH_2 \longrightarrow R{-}C{\equiv}C{-}H$$

$$R{-}C{\equiv}C{-}H \xrightarrow{NaNH_2} RC{\equiv}C^-Na^+ + NH_3$$

$$RC{\equiv}C^-Na^+ + H_2O \rightarrow RC{\equiv}CH + NaOH$$

As the reaction product is the salt of an alkyne, this method can be used to prepare terminal alkynes, even if the triple bond is capable of migration.

$$n\,C_{14}H_{29}CHBrCH_2Br \xrightarrow{NaNH_2} n\,C_{14}H_{29}C{\equiv}CH$$

Inner alkynes can be isomerized to terminal alkynes by reaction with sodium amide at 150 °C [25]:

$$n\,C_5H_{11}C{\equiv}CCH_3 \xrightarrow[150\,^\circ C]{NaNH_2} n\,C_6H_{13}C{\equiv}C^-Na^+ \xrightarrow[-\,NaOH]{+\,H_2O} n\,C_6H_{13}C{\equiv}CH$$

Under normal conditions, unactivated aromatic halides hardly react with nucleophilic reagents, but they are often reactive toward very strong bases [28]. For example, chlorobenzene can be smoothly converted to aniline by reaction with sodium amide in liquid ammonia at − 35 °C:

$$C_6H_5Cl + H_2N^- \longrightarrow C_6H_5NH_2 + Cl^-$$

The corresponding reaction of *p*- chlorotoluene gives both *m*- and *p*-aminotoluene

The *o*-isomer is not formed. The two reaction products do not interconvert under the reaction conditions. The fact that the amide ion deprotonates benzene in liquid ammonia and that this proceeds rapidly in the position *ortho* to halide substituents leads to the conclusion that the amide does not behave as a nucleophilic reagent, but as a base. In this reaction, the hydrogen atom in the *o*-position to the substituent chlorine atom is attacked rather than the carbon atom [28].

Reactions with primary and secondary amines are used in the synthesis of pharmaceuticals [29]. Although lower aliphatic amines [5] do not react with sodium amide at room temperature, aromatic amines undergo a metallation reaction with sodium amide in liquid ammonia or benzene:

$$NaNH_2 + H_2NPh \xrightarrow{C_6H_6} NaNHPh + NH_3$$

Molten $NaNH_2$ attacks primary aliphatic amines, forming cyanamide and a mixture of hydrogen and hydrocarbons. According to [5], it is possible to metallate a primary aliphatic amine with an alkali metal amide in toluene at 50 – 100 °C. A large number of secondary and tertiary heterocyclic amines have been synthesized by the reaction of alkyl and heterocyclic halogen compounds with sodium amide [23]. Tertiary amines containing 2-dialkylaminoethyl groups were tested for antihistamine properties. An example of such a synthesis is given below [23]:

Initiation of Anionic Polymerization. If sodium amide reacts with a suitable alkene (R″ = COOR, CN), the corresponding carbanion is formed, and this initiates the anionic polymerization [26]:

Chain termination is caused by cations [26].

There are detailed accounts of the anionic polymerization of vinyl monomers [37–39] and

of methyl methacrylate [40], [41] in the literature. The preparation of electrically conducting polymers is described in [42, 43].

Amination of Pyridine. The amination of pyridine (Chichibabin reaction) is an example of the nucleophilic reaction properties of sodium amide [44]:

Cleavage of Ketones. The cleavage of ketones by sodium amide is known as the Haller – Bauer reaction [21]:

This reaction can normally only be used with ketones that do not enolize. The ketones are mainly of the type $ArCOCr_3$, and the reaction products, R_3CCONH_2, are not readily obtainable by other methods.

3. Production

Sodium amide is produced from ammonia and sodium using the reaction conditions described by BEILSTEIN and GEUTHER [1] for the reaction

$$2\,NH_3 + 2\,Na \longrightarrow 2\,NaNH_2 + H_2$$

It was known even at that time that the following conditions were essential [1]:

1) Absence of air in the ammonia and reactants
2) Minimum possible water content in the ammonia

During the reaction, ammonia is passed from below through the pre-heated molten sodium in a reactor [45]. The reaction temperature is 300 – 450 °C, preferably between 350 and 400 °C. Decomposition of the molten sodium amide [19] can take place in two ways. If the total gas pressure exceeds the dissociation pressure of sodium hydride, the reaction is

$$NaNH_2 \longrightarrow NaH + 0.5\,N_2 + 0.5\,H_2$$

and below this dissociation pressure, it is

$$NaNH_2 \longrightarrow Na + 0.5\,N_2 + H_2$$

In addition to hydrogen and nitrogen the exhaust gas also contains ammonia [19].

In general, two or more reactors containing alkali metal are arranged in series, so that the unreacted ammonia gas from the first reactor passes through reactors downstream, which reduces the ammonia loss. The hydrogen liberated on formation of the sodium amide passes out of the reactor along with the excess ammonia. The gas mixture passes through a water scrubber to remove ammonia, and the hydrogen that remains is burnt. The aqueous solution of ammonia is processed to enable the ammonia to be totally or partially recycled [46].

When indoxyl is produced by the Heumann – Pfleger process [7], a water-free, ammonia- containing gas mixture is obtained which is used to produce sodium amide. The mixture can contain > 50 % hydrogen. The dust generated in the indoxyl process is removed by filtration, and the gas mixture is passed into the molten sodium through a ring-shaped distributor. The formation of sodium amide is complete after 4 h at 340 – 370 °C; the yield is 97 % [46].

Catalysts [22] strongly accelerate the reaction of sodium with ammonia. The most effective catalysts are iron oxides and the chlorides and nitrates of Fe, Co, and Ni, which are soluble in liquid ammonia. The catalysts added in amounts of < 0.001 mol/g Na, are reduced to the metals. The catalytic action of platinum is reported in [22].

The disadvantage of iron or metal salt catalysts is that removal of the catalyst by filtration is difficult. The catalyst is usually left in the reaction product, although this can cause blockages in valves, pipes, and pumps [47]. In a process for producing alkali metal amides from liquid ammonia and alkali metals, this problem is avoided

by using an alkali metal azide as catalyst. The presence of the azide in the liquid ammonia increases the solubility of the alkali metal amide 20–30 fold. An amide yield of 99.3 % is reported [47]. Residual azide catalyst can be separated from the amide by filtration or centrifugation and recycled.

Other methods of preparation, including laboratory methods for the production of high-purity $NaNH_2$, are described in [19], [22], [23].

4. Safety Aspects

Sodium amide is hygroscopic, and decomposes in moist air [17]. The prolonged action of atmospheric oxygen produces oxidation products such as sodium hyponitrite, $Na_2N_2O_2$, sodium hyponitrate, $Na_2N_2O_3$, etc., [48]. Sodium amide must therefore be stored with exclusion of oxygen and moisture. Careless handling and storage can lead to explosions.

If the skin or mucous membranes come into contact with sodium amide, they must be treated with copious quantities of water.

Sodium amide is flammable. For extinguishing fires, water, carbon dioxide, or halons must not be used under any circumstances, but salt, sodium carbonate, or dry sand are suitable. On heating in the absence of air, $NaNH_2$ decomposes at >400 °C, forming sodium, nitrogen, hydrogen, and small amounts of ammonia.

Sodium amide should be used as soon as possible after manufacture. Products with a yellow or brown appearance must not be used, and must be destroyed. In case of doubt concerning the safety of the material, the melting and burning test should be carried out. For this, ca. 1 g sodium amide is heated in a spoon spatula over a flame. If the material does not melt and burn quietly, but with decrepitation, it is not safe to use. For disposal small amounts of sodium amide can be suspended in dioxan [49], and ethanol can then be added dropwise (for larger quantities, isopropanol is added first). When ammonia evolution ceases, the alkoxide formed is carefully decomposed with water and neutralized, and is then washed into the drainage system with large quantities of water [49]. Larger quantities can be disposed of by burning in a thin layer, e.g., on charcoal, or by spraying with water in a large vessel at a safe distance and in a suitable location.

Sodium amide reacts violently with water, forming sodium hydroxide solution and ammonia. The decomposition products, ammonia and sodium hydroxide, can cause very severe caustic effects, with permanent damage, especially to the skin and mucous membranes [17]. The eyes and respiratory tract are particularly affected. Safety precautions must be taken to protect against danger to the health from contact with ammonia [50]. The precautions for NaOH are those appropriate for caustic materials [51].

5. Uses

An important use for sodium amide is the Heumann–Pfleger indigo synthesis (→Indigo and Indigo Colorants, Chap. 4.), in which phenylglycine salts undergo ring closure in an alkaline melt with liberation of ammonia to form indoxyl [7], [46].

In a state-of-the-art process [52], indoxyl sodium is produced continuously by mixing the molten alkali metal salt of phenylglycine with a molten mixture of sodium amide and alkali metal hydroxide at 230–250 °C in a multiple-screw extruder. The temperature of the molten mixture rises to 260–340 °C in the mixing and reaction zone. The liberated ammonia is drawn off from the degassing zone of the extruder, and can be used directly for the production of sodium amide [52].

The synthesis of carotenoids and vitamins A and D involves the Wittig reaction [26], which can be carried out with sodium amide. In the reaction of methylenetriphenylphosphorane or its derivatives with substituents in the methylene group with carbonyl compounds, the carbonyl oxygen is exchanged with the methylene group, so that triphenylphosphine oxide and the corresponding alkene are formed [53]. For example, in the alkaline medium at room temperature, the reaction of methylenetriphenylphosphorane with benzophenone forms 1,1-diphenylethylene and triphenylphosphine oxide [26]:

$$(C_6H_5)_3P{=}CH_2 + O{=}C(C_6H_5)_2 \longrightarrow (C_6H_5)_3P{=}O + H_2C{=}C(C_6H_5)_2$$

When methyltriphenylphosphonium bromide in a suitable solvent is treated with an equivalent of a strong base B (e.g., phenyllithium, sodium ethoxide) the base deprotonates the salt, and an

equilibrium reaction then takes place forming methylenetriphenylphosphorane [53]:

WITTIG et al. [53] suggested that sodium amide in liquid ammonia could be used to form the ylide. The ammonia is then replaced with ether or THF [54].

When lithium alkyls are used as base [55], the corresponding lithium halide is formed, which lowers the stereoselectivity of the reaction. The development of "salt-free" ylide solutions, prepared, for example, by using sodium amide, allowed stereoselective Wittig reactions to be carried out [55]. According to [21], [56], if the base does not contain lithium, the ylide is said to be prepared under salt-free conditions.

It became apparent that most triphenylphosphonium salts with a negative charge on the α-carbon atom react even with weaker bases than phenyllithium, yielding the corresponding ylides, usually in good yields [57], [58]. Suitable proton acceptors include alkali metal alkoxides and sodium amide [57], [59].

When sodium ethoxide or methoxide is used as a proton acceptor [53], [58] with the corresponding alcohol as solvent, the alcoholate anion removes a proton from the phosphonium salt. The methylenetriphenylphosphorane is formed in solution according to the equation:

The ylides can be prepared by mixing the phosphonium salt with a stoichiometric amount of powdered sodium amide [21], [60]. The ylide can be liberated by adding a layer of diethyl ether or tetrahydrofuran [52]. The alkene can then be obtained in good yield by reaction with an aldehyde or ketone [60].

Sodium amide is used in the production of pharmaceuticals and intermediates. The papers and patents quoted in [29] can be divided into:

1) Reactions of sodium amide with secondary or primary amino groups
2) Reactions with active C – H groups
3) Addition reactions

1) Phenothiazine (or its derivatives) is first reacted with sodium amide, and then with an organic halogen compound:

The derivatives of phenothiazine are used as ganglion blockers, local anaesthetics, and particularly antispasmodics [30].

The reaction with other secondary amines, e.g., azepine derivatives, substituted aminopyridines, or anilines to give derived products can be represented as follows [31]:

The products derived from the resulting azepine derivatives have antiallergic, sedative, or antispasmodic properties.

Only a few examples exist for the reaction of $NaNH_2$ with primary amines, 2-aminopyridine, or acid amides according to the scheme [32]:

2) There are many reports dealing with the reaction of phenylacetonitrile and its derivatives [23] with $NaNH_2$, sometimes followed by reaction with a halogen compound [33]:

Antitussive, antihistamine, and analgesic effects have been claimed for this product group.

The introduction of another substituent into the CH group of diphenylacetonitrile can be achieved by the following reaction scheme:

These reactions are mainly used as stages in the manufacture of antispasmodics, analgesics, and antidiarrhoics [34].

The deprotonation of alcohols by sodium amide is the basis for the preparation of antihistamines, antispasmodics, and an antitussive. These reactions take place according to the following scheme [35]:

$R'OH + NaNH_2 \longrightarrow R'ONa + NH_3$

$R'ONa + R''Cl \longrightarrow R'OR'' + NaCl$

3) An addition reaction of 2-chlorobenzophenone with acetonitrile [23] takes place in the presence of $NaNH_2$ as base [4], [36]:

A further use for sodium amide is in halogen – NH_2 exchange reactions in aromatic chemistry [61]. These reactions between halogenated aromatics and alkali metal amides are carried out in liquid ammonia and apparently involve aryne intermediates. For example, when 1-bromo-2,4-dichlorobenzene reacts with $NaNH_2/NH_3$ in the molar ratio 1 : 2 – 1 : 7, 3,5-dichloroaniline is produced in 70 % yield:

Under comparable conditions, *m*-chloroaniline can be obtained from *o*-dichlorobenzene (yield: >70 %, purity: >98 %) [61].

Sodium amide is also used as a starting material for the production of sodium azide (→Hydrazoic Acid and Azides, Chap. 4.1.) [2]. In this process, powdered $NaNO_3$ is added to molten $NaNH_2$ at 175 °C, or N_2O is passed through molten sodium amide at 190 °C:

$3\,NaNH_2 + NaNO_3 \longrightarrow NaN_3 + 3\,NaOH + NH_3$

$2\,NaNH_2 + N_2O \longrightarrow NaN_3 + NaOH + NH_3$

In the latter reaction, the $NaNH_2$ can be produced in situ from liquid ammonia and sodium [2]. Sodium azide catalyzes the reaction [47].

6. Transport Regulations

During the storage and transportation of sodium amide, moisture and air must be excluded by inertizing with a protective gas (e.g., nitrogen) or protective liquid (e.g., inert hydrocarbons) [62].

The transport regulations (1993) classify sodium amide as follows:

European land transport (RID/ADR):	Class 4.3, No. 19 b.
Sea transport (IMDG Code):	Class 4.3, UN No. 1390 PG.II
Air transport (ICAO-TI/IATA-DGR):	Class 4.3, UN No. 1390 PG. II

Apart from the maximum allowable amounts per package, the packaging regulations for the various carriers have been harmonized. In general, the packages must be UN approved and hermetically sealed against water vapor.

For transport by passenger aircraft (unlike freight-only aircraft), only assembled packages are permitted.

Intermediate bulk containers (IBCs) may not normally be used for the land or air transport of sodium amide, but metal IBCs are permitted for sea transport if they are UN approved and hermetically sealed.

Movable containers (tanks) are not permitted for sodium amide.

1. Introduction

Sodium is the best-known alkali metal. The amount of sodium metal produced industrially exceeds that of all other alkali metals. It is a member of group 1 of the periodic table, with the relative atomic mass 22.9898 and the atomic number 11.

Sodium has only one naturally occurring isotope, ^{23}Na. Several artificial isotopes are also known [1]. The isotope ^{24}Na is used as a tracer in industrial and medicinal applications.

Few basic chemicals are used in as many areas as sodium metal. Elemental sodium can be considered both a fine chemical whose properties make it indispensable for industrial applications ranging from pharmaceuticals to heavy inorganic chemicals, and a readily liquefied metal with a wide range of metallurgical and physical uses. A large number of products derived from sodium metal are used in the chemical industry.

History. The German name *Natrium* is derived from the Egyptian *neter,* meaning sodium carbonate [2–4], while the English name sodium is derived from soda [3]. Sodium was discovered in 1807 by Davy, who electrolyzed molten sodium hydroxide in a platinum dish, by contacting it with a platinum wire using a voltaic pile as the source of electricity [3].

However, this electrolytic process could not be used for industrial production at that time, because no economic source of direct current was available. Powerful d. c. generators first became available after the discovery of the dynamo principle by W. von Siemens in 1867.

The history of the industrial production of sodium, which extends over more than 100 years, can be divided into four periods, in which four different processes were used [5].

Thermochemical reduction processes were used between 1854 and 1890. A mixture of sodium carbonate, wood charcoal or coal, and quicklime was heated to $>1100\,^{\circ}$C, and the sodium vapor formed was condensed (Sainte. Claire Deville, Paris, 1854). An annual production of 5 – 6 t of sodium was achieved by this process. In a later development, sodium carbonate was replaced by sodium hydroxide, and the wood charcoal or coal by a mixture of iron and coal (Castner, 1886). Using this process, the Aluminium Company Limited in Oldbury produced ca. 150 t/a sodium between 1888 and 1890 [4].

Between 1891 and 1920, sodium was produced by electrolysis of molten sodium hydrox-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_277

ide, to which sodium chloride and sodium carbonate were added to lower the melting point (Castner process). The Castner process [6] (see Section 4.2.1) was the only important industrial process for producing sodium during this period.

In the 1900s, attempts were made in Switzerland (Ciba), Germany (Degussa), and the United States (Rössler & Hasslacher Chemical Co.) to use the cheaper starting material sodium chloride in a molten salt electrolysis process. In 1921, Downs succeeded in constructing a cell for electrolyzing sodium chloride [7], the basic principle of which is still used today. The electrolyte used from ca. 1925 onward for industrial production was a mixture of sodium chloride and calcium chloride. Since ca. 1950, a modified Downs cell has been used, with an electrolyte consisting of a ternary mixture of NaCl, $BaCl_2$, and $CaCl_2$. This process has since become established worldwide (see Section 4.2.2).

The industrial use of sodium has also undergone a change. The only demand for large-scale production of sodium in the mid-1800s came from the aluminum industry, where it was used for reducing aluminum trichloride. However, around 1890, aluminum producers began to switch to a molten salt electrolysis process. Sodium was also used in the production of sodium cyanide (for extracting gold from its ores) and sodium peroxide. It was later used in the production of lead- containing antiknock agents for gasoline and special metals such as titanium.

2. Properties

Physical Properties. The properties of sodium are directly related to its structure [8]. The electronic configuration of sodium is $1s^2\,2s^2\,2p^6\,3s^1$. The atomic volume is therefore large, and the cohesive forces in the sodium lattice are relatively low. Thus, like all alkali metals, sodium has a lower density than the alkaline-earth metals, as well as lower hardness; lower melting and boiling points; and lower energies of sublimation, vaporization, and dissociation [5], [9].

Sodium crystallizes from the melt with a body- centered cubic crystal lattice. It has typical metallic properties, including high thermal and electrical conductivity, the electrical conductivity of sodium at 20 °C being about one-third that of copper. It is liquid over a wide temperature range from 97.8 to 881.4 °C and has a fairly low vapor pressure, which is an important requirement for production in an electrolytic cell [10].

Alkali metals give characteristic flame coloration. Their outer electrons can easily be raised to an excited state, which is the basis for their analytical determination by flame photometry and atomic absorption spectroscopy. Sodium and sodium salts color the flame of a Bunsen burner yellow. The sodium D doublet at 589 and 589.6 nm is due to the $3s^1 - 3p^1$ transition in sodium atoms formed by the reduction of Na^+ in the flame [9].

Sodium is monatomic in the vapor state, although dimers and tetramers have also been reported [10].

Some physical properties of sodium are listed below [8], [10]:

Atomic number	11
Relative atomic mass	22.98977
Melting point	97.83 °C
Heat of fusion	113 J/g
Volume expansion on melting	2.7 %
Boiling point	881.4 °C
Heat of vaporization	3750 J/g
Atomic radius in metallic lattice	189.6 pm
Ionic radius	95 – 98 pm
Ionization potential	5.139 V
Standard electrode potential	2.714 V
Electrical resistivity at 293 K	$4.77 \times 10^{-8}\ \Omega \cdot m$
Critical temperature	2508.7 ± 12.5 K
Critical pressure	25.64 ± 0.02 MPa
Critical density	206 kg/m^3
Specific heat capacity at 293.15 K	1.22 J g^{-1} K^{-1}
Thermal conductivity at 293.15 K	132.3 W m^{-1} K^{-1}
Density	
at 293.15 K	0.968 g/cm^3
at 393.15 K	0.927 g/cm^3

The density (kilograms per cubic meter) of solid sodium in the range 273 – 370.98 K is given by the following equation [8]:

$$\varrho_T = 972.5 - 20.11 \times 10^{-2}\,(T - 273.15) \times 10^{-4}\,(T - 273.15)^2$$

For liquid sodium in the range 370.98 – 1644.24 K, the following equation applies [8]:

$$\varrho_T = 1011.8 - 0.22054T - 1.9226 \times 10^{-5}T^2 + 5.637 \times 10^{-9}T^3$$

The specific heat capacity ($J\,g^{-1}\,K^{-1}$) as a function of temperature at 273.15 – 370.98 K is given by [8]

$$c_p = 1.1987 + 6.4894 \times 10^{-4}\,(T - 273.15) + 1.053 \times 10^{-5}\,(T - 273.15)^2$$

In the range 370.98 – 1173.15 K, the following equation applies [8]

$$c_p = 1.4361 - 5.8024 \times 10^{-4}\,(T - 273.15) + 4.621 \times 10^{-7}\,(T - 273.15)^2$$

The thermal conductivity ($W\,m^{-1}\,K^{-1}$) from 370.98 to 1173.15 K is given by [8]

$$\lambda = 91.8 - 4.9 \times 10^{-2}\,(T - 273.15)$$

The vapor pressure (kilopascals) at 300 – 2500 K is [8]

$$\log p = 10.182516 - (5693.8776/T) - (1.0948 \log T) + 8.5874946 \times 10^{-5}T$$

The viscosity ($mPa \cdot s$) at < 773 K is given by [8]

$$\eta = (0.1235 \pm 0.0018) \cdot (\varrho/1000)^{1/3} \cdot \exp\frac{(697 \pm 9)}{1000T}$$

Above 773 K, the equation is [8]

$$\eta = (0.0815 \pm 0.0013)\,(\varrho/1000)^{1/3} \cdot \exp\frac{(1040 \pm 19)}{1000T}$$

The surface tension (newtons per meter) in the range 370.98 – 1300 K is given by [8]

$$\sigma = 206.7 \times 10^{-3} - 1.0 \times 10^{-4}\,(T - 273.15)$$

Figure 1 shows some properties of sodium as a function of temperature.

Chemical Properties. The reactivity of sodium can be illustrated by the following equations [12], [13]:

$$2\,Na + H_2 \rightleftharpoons 2\,NaH$$

$$4\,Na + TiCl_4 \rightleftharpoons Ti + 4\,NaCl$$

$$2\,Na + 2\,NH_3 \longrightarrow 2\,NaNH_2 + H_2$$

$$2\,Na + O_2 \longrightarrow Na_2O_2$$

$$2\,Na + 4\,S \longrightarrow Na_2S_4$$

$$2\,Na + X_2 \longrightarrow 2\,NaX\ (X = \text{halogen})$$

$$Na + ROH \longrightarrow RONa + 1/2\,H_2$$

$$2\,Na + 2\,RX \longrightarrow R{-}R + 2\,NaX$$

(X = halogen, R = alkyl group)

The high reactivity of sodium is a result of its electronic configuration [14]. Sodium, like the other alkali metals, has only one *s* electron in its outer shell, which is very weakly bound due to shielding from the atomic nucleus provided by the completely filled rare gas shells.

1) Sodium reacts with hydrogen at ca. 200 – 300 °C to form sodium hydride. In NaH, hydrogen is present as hydride ion. In organic syntheses, sodium hydride has little reducing action [15], its most important chemical property being high basicity. Sodium hydride reacts as a strong base not only with all acids, but also with all organic and inorganic compounds that contain an active hydrogen atom. Sodium hydride is more strongly basic than sodium amide [16]. However, in molten NaOH or eutectic salt baths, NaH behaves as a strong reducing agent toward metallic salts and oxides [17]. The system $Na - H_2 - NaOH - Na_2O$ has been investigated extensively [18], [19].
2) Titanium was first produced in large quantities in 1910 by HUNTER, who reacted titanium tetrachloride with sodium in an evacuated steel bomb. In 1956, ca. 1500 t of titanium sponge, representing ca. 10 % of the total world output, was produced by ICI by reducing titanium tetrachloride with sodium [20]. Also, Reactive Metals, Inc., of Ashtabula, Ohio, until recently, used sodium as the reducing agent in the production of titanium. However, by far the largest amount of titanium has been produced by the magnesium-based Kroll process. More recently, the electrolysis of $TiCl_4$ has become important.

Figure 1. Some properties of sodium as a function of temperature [11]
A) Density; B) Specific heat capacity; C) Thermal conductivity; D) Viscosity; E) Surface tension; F) Vapor pressure

The Hunter process is representative of many reactions in which the halides of most of the metals in periods 4 – 6 of the periodic table can be reduced with sodium to the metal, with formation of the corresponding sodium salt. Examples include the production of aluminum by using sodium as the reducing agent (Deville and Bunsen process, 1854) [4] and of thorium from thorium tetrachloride [4], [21–23] or K_2ThCl_6 [24]. The elements potassium, beryllium, magnesium, boron, and aluminum can also be produced by this method. The reduction of KCl by sodium appears to go against the normal order of reactivity (K > Na). At 850 – 880 °C, the following reaction takes place:

$$Na\,(gas) + K^+\,(liquid) \rightleftharpoons Na^+\,(liquid) + K\,(gas)$$

Since potassium is more volatile, it is more readily distilled, so the equilibrium is shifted to the right and the reaction proceeds [9].

3) Sodium amide is produced industrially by the reaction of molten sodium with ammonia at 300 – 400 °C.
Sodium dissolves in liquid ammonia to give a blue color that changes to a coppery red with increasing concentration. Solutions of alkali metals in liquid ammonia are powerful and selective reducing agents. Aromatic systems are reduced smoothly to cyclic mono- or dialkenes, and alkynes are stereospecifically reduced to *trans*-alkenes [9].
Sodium does not react with molecular nitrogen under normal conditions. Hence, nitrogen is a suitable protective gas, even at high temperature, for the production, storage, and transport of sodium [10].
Sodium azide, NaN_3, can be prepared by the reaction of dinitrogen oxide with sodium amide at 200 °C. The existence of Na_3N is very doubtful. The heavier alkali metals do not appear to form compounds of this type, possibly for steric reasons [9].
Prior to the 1960s (i.e., before modern catalytic methods for producing hydrogen cyanide became available [12]), sodium cyanide was produced via sodium amide and sodium cyanamide by the Castner process [12]:

$$\begin{array}{l} 2\,Na + 2\,NH_3 \longrightarrow 2\,NaNH_2 + H_2 \\ 2\,NaNH_2 + C \longrightarrow Na_2N_2C + 2\,H_2 \\ Na_2N_2C + C \longrightarrow 2\,NaCN \\ \hline 2\,Na + 2\,NH_3 + 2\,C \longrightarrow 2\,NaCN + 3\,H_2 \end{array}$$

Metallic silver and gold form complexes with NaCN in a smooth reaction under mildly oxidizing conditions. This is used in the extraction of these metals from ores or gold-bearing sand [12].
With carbon, sodium forms compounds of the acetylide type, M_2C_2, and with graphite it forms a layered compound [8]. Sodium acetylide can be produced by the reaction of sodium with acetylene or by the thermal decomposition of $NaHC_2$ in a vacuum. Sodium acetylide can be used in the preparation of alkynes.
The reaction between graphite and sodium gives an intercalation compound with the approximate formula $C_{64}Na$ [8].
Sodium formate or oxalate can be produced in the reaction between carbon dioxide and sodium. Burning sodium reacts explosively with solid carbon dioxide; thus CO_2 extinguishers are unsuitable for sodium fires [10]. Alkali metals in liquid ammonia react with carbon monoxide to form colorless crystals of $Na_2C_2O_2$, which contain linear groups, NaOC≡CONa, linked together to form chains [9].

4) Sodium reacts with oxygen to form the following oxides: monoxide (Na_2O), peroxide (Na_2O_2), and hyperoxide (NaO_2). The ozonide NaO_3 is also known [25].
The reactions to form the monoxide and the peroxide are exothermic. The peroxide is manufactured in a rotating drum reactor. In the first stage, sodium reacts with air to form sodium monoxide, which reacts with oxygen or oxygen-enriched air in the second stage to form sodium peroxide [25].
The structure and chemical properties of the oxygen compounds of alkali metals have been investigated thoroughly [26].
In normal atmospheric air, molten sodium can ignite at >115 °C, but higher temperature is necessary in dry air. Combustion is exothermic, with the evolution of much smoke, and an intense white-yellow light is emitted with the formation of Na_2O and Na_2O_2 [10].
Sodium reacts with water to form sodium hydroxide and hydrogen. If the hydrogen evolved mixes with air, the gas mixture formed can explode with great violence [10].
The reaction of excess sodium with high-pressure steam in the absence of air gives sodium hydroxide and sodium hydride [8].
The heats of reaction of the individual reaction steps are given below [8]:

$$Na_{(l)} + H_2O_{(l)} \longrightarrow NaOH_{(s)} + 1/2\,H_2,$$

$$\Delta H^0_{298} = -145\,kJ/mol$$

$$Na_{(l)} + H_2O_{(g)} \longrightarrow NaOH_{(s)} + 1/2\,H_2,$$

$$\Delta H^0_{298} = -185.4\,kJ/mol$$

$$2\,Na_{(l)} + H_2O_{(g)} \longrightarrow NaOH_{(s)} + NaH_{(s)},$$

$$\Delta H^0_{298} = -\,195.3\ \text{kJ/mol}$$

$$Na_{(l)} + 1/2\,H_2 \longrightarrow NaH_{(s)},$$

$$\Delta H^0_{298} = -\,56.4\ \text{kJ/mol}$$

$$Na_{(l)} + NaOH_{(s)} \longrightarrow Na_2O + 1/2\,H_2,$$

$$\Delta H^0_{298} = +\,10.7\ \text{kJ/mol}$$

$$2\,Na_{(l)} + H_2O_{(g)} \longrightarrow Na_2O_{(s)} + H_2,$$

$$\Delta H^0_{298} = -\,128.1\ \text{kJ/mol}$$

$$2\,Na_{(l)} + NaOH_{(s)} \longrightarrow Na_2O_{(s)} + NaH_{(s)},$$

$$\Delta H^0_{298} = -\,45.7\ \text{kJ/mol}$$

5) Molten sodium reacts with stoichiometric amounts of molten sulfur under an inert atmosphere to form disodium tetrasulfide.
$2\,Na + 4\,S \longrightarrow Na_2S_4$
Disodium tetrasulfide is used industrially for the production of organofunctionalized silanes [27] by reaction with 3-chloropropyltrialkoxysilanes. In a nucleophilic reaction, the tetrasulfide anion displaces the chlorine atoms and links two propyltrialkoxysilane molecules with formation of a sulfur bridge [27].

$$2\,(RO)_3{-}Si{-}(CH_2)_3{-}Cl + Na_2S_4 \longrightarrow (RO)_3Si{-}(CH_2)_3{-}S_4{-}(CH_2)_3{-}Si(OR)_3 + 2\,NaCl$$

6) Halogens react with sodium with varying degrees of vigor. With fluorine, ignition takes place at room temperature, but no reaction occurs in liquid chlorine. With gaseous, dry chlorine, negligible reaction takes place at room temperature, but molten sodium burns in a stream of chlorine to form sodium chloride. This reaction takes place to a small extent in the Downs cell. Sodium is fairly stable toward bromine. Sodium and iodine can be melted together without reaction [10].

7) Lower and primary alcohols react readily with sodium to form alkoxides. Higher and branched alcohols generally react very slowly due to the decreasing acidity of the hydroxyl group. The reaction velocity can be increased by raising the temperature and by using finely divided sodium. Alkoxides are condensation agents of high basicity, used in the alkylation of carbon, nitrogen, and oxygen atoms (e.g., the mono- and dialkylation of malonic esters, acetoacetic esters, cyanoacetic esters, benzyl nitrile) and for base- catalyzed ring closure reactions to form nitrogen- containing heterocyclic compounds. Alkoxides are used as synthetic building blocks in the Williamson ether synthesis [11].

8) The reactions of alkali metals with alkyl halides (Wurtz reaction) are heterogeneous and probably very complex [28]. Alkanes are formed when the alkylsodium compound initially formed displaces the halogen atom from an alkyl halide molecule:

$$R{-}X + 2\,Na \longrightarrow R^-Na^+ + NaX$$

$$R^- + RX \longrightarrow R{-}R + X^-$$

Organometallic compounds of group IV A metals can be prepared by a variation of this synthetic method. For example, tetraethyllead can be prepared by reacting chloroethane with a lead sodium alloy [29]:

$$4\,C_2H_5Cl + 4\,Na{-}Pb \longrightarrow (C_2H_5)_4Pb + 3\,Pb + 4\,NaCl$$

3. Occurrence

Sodium is strongly electropositive, very reactive, and does not occur in nature in the elemental state, but always in cationic form in salts. Sodium is the seventh element in order of abundance in the Earth's crust (2.27 wt %). It occurs in several minerals in association with other alkali metals. Extensive deposits of relatively pure sodium salts were formed by the evaporation of prehistoric lakes, a process that can still be observed [e.g., in the Great Salt Lake (Utah) and the Dead Sea].

Industrially important naturally occurring sodium compounds include rock salt (sodium

chloride), trona (sodium carbonate), Chile saltpeter (sodium nitrate), mirabilite (sodium sulfate), and borax or kernite (sodium borate). Sodium chloride (NaCl) is the most used raw material in the inorganic chemical industry [9].

4. Production

4.1. Chemical Processes

Sodium can be obtained from many of its compounds by high-temperature reduction [4]. In the older thermochemical methods, sodium carbonate or sodium hydroxide was reacted with charcoal or coal, sulfur, or iron. Other compounds of sodium, such as the chloride, sulfide, sulfate, and cyanide were also used. A serious disadvantage of thermochemical methods was that reverse and secondary reactions occurred. Despite these problems, patents were applied for, covering many variations of the thermochemical methods of production [10]. In a Du Pont patent, sodium carbonate or sodium hydroxide was reduced with coal. The gases formed in the reaction were passed through molten tin, which absorbed the sodium vapor. Sodium was then recovered from the tin in an additional process step. According to a patent of Pechiney S. A., NaCl vapor is passed over calcium carbide at 800 – 1000 °C, and the sodium formed is collected in oil. In a Dow Chemical Co. process, sodium carbonate is reduced with coal at > 1200 °C. The sodium vapor formed is condensed in liquid sodium [10].

4.2. Electrolytic Processes

4.2.1. Development of Molten Salt Electrolysis of NaOH and NaCl

Using the same principle by which Davy discovered sodium, Castner developed a process for producing the metal on a large scale from molten sodium hydroxide in an electrolytic cell (Fig. 2). This process was operated at Niagara Falls (United States) and Rheinfelden (Germany), and was the only practical method for sodium production from 1881 to the mid-1920s. Cheap hydroelectric power was available at both locations.

Figure 2. Production of sodium by the Castner process (1891)

The Castner process yields sodium, hydrogen, and oxygen:

$$4\,Na^+ + 4\,e^- \longrightarrow 4\,Na \text{ (cathode)}$$

$$4\,OH^- \longrightarrow 2\,H_2O + O_2 + 4\,e^- \text{ (anode)}$$

$$2\,H_2O + 2\,Na \longrightarrow 2\,NaOH + H_2$$

The overall reaction is:

$$4\,NaOH \longrightarrow 2\,Na + 2\,NaOH + H_2 + O_2$$

Thus the current efficiency cannot exceed 50 %. In practice, current efficiencies of <45 % were achieved.

Before sodium can be produced by this method, sodium hydroxide must first be obtained (e.g., by electrolysis of aqueous sodium chloride). Much research was therefore aimed at producing sodium by direct electrolysis of sodium chloride, which has the following advantages over sodium hydroxide as a starting material:

1) Higher current efficiency during sodium production

2) Cheaper raw material
3) Easier handling
4) Production of chlorine as byproduct

Its disadvantages are:

1) The need to install a plant for chlorine purification and sometimes also for chlorine liquefaction
2) Increased technical problems associated with chlorine
3) Higher melting point

Many cells were developed at this time, but only the Downs cell solved the problems encountered with other cells. With the Downs cell, the foundations were laid for large-scale sodium production. Along with the Hall aluminum cell and the Dow magnesium cell, this is one of the most successful molten salt electrolysis cells ever developed [30].

Figure 3. The Downs cell (original form)
a) Steel vessel; b) Ceramic lining; c) Iron cathode; d) Graphite anode; e) Wire gauze diaphragm; f) Dome for collecting chlorine gas; g) Insulating lid; h) Channel with riser pipe for collecting sodium; i) Sodium overflow; j) Sodium holding vessel

In the Castner cell (Fig. 2) a cylindrical nickel anode surrounds the copper cathode concentrically. If NaOH is replaced by a molten salt containing NaCl, the collection and containment of the chlorine evolved cause problems, which are solved only when the positions of the anode and cathode are reversed, as in the Downs cell in which the anode is surrounded concentrically by the cathode.

Figure 3 is a schematic of the Downs cell in its original form [13], [31]. It consists of a lined steel vessel in which the graphite anodes pass through the floor, and the two electrical conductors connected to the cathodes pass through the walls. The anode is surrounded by the cylindrical iron cathode.

The Downs process used a mixture of 60 wt % $CaCl_2$ and 40 wt % NaCl at an operating temperature of 560 – 585 °C. This composition represents a compromise between the melting point of the salt mixture and the sodium content. The eutectic mixture, which contains 66.8 wt % $CaCl_2$ and 33.2 wt % NaCl, melts at ca. 505 °C. Although increasing the $CaCl_2$ content reduces the melting point of the binary mixture, it also decreases the concentration of sodium in the cathode space due to the equilibrium

$$2\,Na + CaCl_2 \rightleftharpoons 2\,NaCl + Ca$$

The operating temperature of ca. 580 °C is well below the temperature of maximum solubility of sodium in the molten salt. The density of the salt is 1.89 – 1.94 g/cm^3. Along with sodium metal, calcium (ca. 3.5 – 4 wt %) is deposited at the cathode. Because of the high melting point of calcium (804 °C) and its low solubility in sodium (see Fig. 6), the alloy phase Na – Ca can accumulate in the sodium and cause blockages in the equipment for continuous removal of sodium from the cell. These solid deposits must be scraped off the walls of this equipment. Most of the calcium can react with NaCl in the melt (by the above reversible reaction), again forming calcium chloride. A further quantity of calcium is removed from the sodium by filtration at 110 °C. The sodium purified in this way contains <400 ppm calcium. Some of the early cell types used for sodium production (e.g., the Castner, Ciba, McNitt, and Downs cells) are described in detail in [4], [13].

4.2.2. Description and Operation of NaCl Molten Salt Electrolytic Cell

Large sodium production plants have 40 – 50 d. c. electrolytic cells connected in series to achieve optimum efficiency. The voltage of each cell depends on the operating conditions (current, temperature, melt composition, sodium production rate) and changes with time.

Electrolytic cells are usually operated at up to 45 kA, with outputs of up to 800 kg/d sodium. For problem-free operation, the individual electrolytic cells, with their associated equipment, must be electrically insulated from neighboring cells and from the ground. The graphite used to make the anodes in the electrolytic cell is resistant to nascent chlorine in the chloride melt even at high temperature, and its electrical conductivity is adequate at the operating temperature. However, all oxygen- containing compounds must be removed from the salts used to prevent corrosion of the graphite. Salts of heavy metals and salts of aluminum and magnesium also cause problems in molten salt electrolysis.

Because of the requirement for high-purity raw materials, extensive facilities are required to purify the salt used in the electrolytic process [5]. Sodium chloride is first dissolved in water to give a saturated brine. Barium chloride and sodium carbonate are added, mainly to remove $CaSO_4$. The precipitate of $BaSO_4$ and $CaCO_3$ forms a sediment together with clay minerals present in the crude salt. The filtered solution is then evaporated to crystallize the salt, which is recovered by centrifugation and dried to a water content of <600 ppm, which is important for optimum operation of the electrolytic cells [5]. A process for the purification of sodium chloride by recrystallization alone, without the use of precipitating agents, has been reported [32]. A schematic of a sodium production process is given in Figure 4.

At the melting point of sodium chloride (808 °C), chlorine would severely corrode all the cell components that come in contact with it. Also, the vapor pressure of sodium is high at this temperature (50 kPa), and its solubility in molten salt is also high (4.2 wt %). Therefore lower melt temperatures must be used. A ternary salt mixture is normally employed ($NaCl - BaCl_2 - CaCl_2$). The temperature of the molten salt in the cell is ca. 600 °C.

From this molten salt mixture, ca. 1 % calcium is deposited on the cathode with the sodium. The crude sodium removed from the cell also contains 0.3 wt % calcium oxide, 0.3 wt % sodium oxide, and small quantities of entrained molten salt. A product of marketable quality [10] is made by cooling the sodium to ca. 120 °C and removing the impurities that separate with the aid of a candle filter equipped with gauze. The filter cake obtained consists of calcium, sodium, chlorides, and oxides. Various methods of recovering calcium or calcium alloys from the filter cake have been proposed, but none has had commercial success [1], [33], [34].

In modern cells (Fig. 5) the cathode and anode are subdivided into four pairs of electrodes. Four steel tubes, welded together, surround the four cylindrical graphite anodes concentrically. The cell design has been developed over the course of time [13], [35–40].

The anodes usually take the form of a hollow cylinder with slits in the wall [41], [42]. Alternatively, anode blocks can be made with conical central holes, which increases the proportion of graphite and decreases the resistance along the length of the anode [43].

The four steel cathodes are connected to the electrical supply by two conducting rods that pass through the side walls of the cell. The annular gap between the anode and the cathode is < 50 mm wide. A cylindrical iron mesh is placed in this gap, forming a diaphragm to separate the products, sodium and chlorine. The cylindrical diaphragm is attached to a device that collects sodium and chlorine from the four electrode pairs. Above the cathode space (between the cathode and the diaphragm) is a channel with a closed roof to collect the liquid sodium that rises through the melt in the form of droplets. Four shafts lead gaseous chlorine from the four anode spaces upward into a dome. Chlorine collects in the dome above the surface of the melt and is removed via an outlet at the top.

The chlorine pipe leading from the top of the dome is fitted with an access cover that is used to monitor the extraction of chlorine from the cell into the collection device. This cover can be provided with a tongue-and-groove seal to prevent intake of air into the chlorine [44].

The roof of the sodium- collecting device usually slopes upward, so that sodium flows smoothly into the vertical riser pipe. The device for collecting the sodium and chlorine may also include a tube for promoting circulation of the melt. The chlorine bubbles that form and rise at the graphite anodes improve the circulation of the melt in the anode space. The rising gas bubbles cause the surface of the melt to rise in the chlorine collection hood, so that the salt level is higher inside the hood than outside. Circulation of the molten catholyte is improved by the up-

ward flow of the sodium. Downward flow of the catholyte takes place by natural convection at the inactive outer walls of the cathodes. By including a circulation tube, the flow of the catholyte can be improved, enabling the electrolyte from the chlorine- collecting hood to flow downward into the central cathode space [45].

Sodium flows from the riser pipe of the collecting device into a closed collection vessel [6]. The calcium dissolved or suspended in the sodium separates as a solid on the inner walls of the riser pipe. Blockage is prevented by means of an agitator inside the riser pipe that scrapes calcium from the walls. Since the density of calcium is higher, it sinks down through the sodium to the salt level, where partial reaction with NaCl of the ternary salt mixture occurs to form calcium chloride and sodium. Various designs of this agitator mechanism in the riser pipe have been described [46], [47]. Calcium, oxides (e.g., Na_2O_2 and CaO), and entrained melt settle at the bottom of the collection vessel, which is therefore equipped with a stirrer [48]. A design has also been described in which this stirrer is combined with the agitator in the riser pipe [49].

A characteristic of another possible design [49] is, that the open overflow is replaced by an overflow pipe between riser pipe and collecting vessel (see Fig. 5).

If the overflow pipe is at the correct height, the hydrogen liberated occasionally at the cathode and the chlorine diffusing into the cathode space do not enter the collector. The gases that collect above the sodium in the gas space of the riser pipe are removed by a stream of inert gas (e.g., nitrogen) [50].

An overview of the procedures for starting up a Downs cell is given in [51].

The salt used for the initial melting operation can be a solid salt mixture or a powdered, solidified melt. Melting is achieved by short-circuiting the electrodes with so- called starter blocks. A number of these starter blocks are wedged between the anode and cathode, and the cell is then filled with salt mixture. In order to melt the mixture, a low electric current is passed through the cell. When sufficient salt has melted, the starter blocks are removed, the current is increased to the normal operating level, and the diaphragm is inserted.

In an improved technique, the cell is filled with solid powdered electrolyte or salt mixture until the level is just below the top of the electrodes [52]. The part of the cathode that is not co-

Figure 5. Modified Downs cell
a) Anode; b) Cathode; c) Molten salt; d) Diaphragm; e) Chlorine dome

vered is then heated to a temperature well above the melting point of the salt mixture. If a small amount of liquid melt is introduced from another cell, a low electric current can be passed between the electrodes. While solid salt mixture is being added, the electric current is slowly increased until the cell is filled with molten salt mixture to the correct height. The diaphragm is then introduced. A further improvement in the procedure for starting up a cell has now been developed, in which the cell is preheated, and sufficient liquid melt from neighboring cells is added to enable the diaphragm to be introduced and the electric current to be applied immediately to the cell [51]. Sodium production can then begin without the need for the complicated procedures described above.

Cells normally have a capacity of ca. 8.4 t molten salt with a density of ca. 2.7 g/cm^3. Cells have a working life of about three years. They are normally taken out of commission when the cell voltage and hence the energy consumption become too high due to wear of the anodes. Operating data for a Downs molten salt cell are [5]:

Operating temperature	590 – 610 °C
Lifetime of cell	1100 – 1200 d
Cell voltage	6.5 – 7 V
Cell current	$\leq$ 45 kA
Current efficiency	80 – 90 %
Consumption of electrical energy	9.8 – 10.5 kW · h/kg Na

The voltage required for the electrolysis of sodium chloride is ca. 3.4 V, which is ca. 50 % of the cell voltage.

In the course of a working life, various changes in the operating conditions of the Downs cell take place that lead to increased energy consumption. These changes are mainly a result of loss of graphite from the anodes due to corrosion and erosion, and buildup of impurities in the melt, leading to the accumulation of precipitated material on the cell floor [53]. A cell that consumes ca. 280 kWh per day to produce 700 kg sodium uses ca. 116 kWh for decomposing the NaCl to sodium and chlorine, which corresponds to a power efficiency of ca. 41 %. Heating the charge of NaCl from room temperature to the operating temperature requires 9.9 kWh, and an additional 11.1 kWh is required for melting, amounting to ca. 8 % of the total power consumption. To maintain a constant melt temperature, a cooling power of 143 kWh is required (i.e., ca. 51 % of the total power consumption). The difficulty in operating a cell consists in maintaining an optimum balance of the continually changing rate of heat production due to the internal resistance of the cell, recombination of sodium and chlorine to form sodium chloride, and the rate of removal of excess heat. Here, care must be taken that the flow pattern and hence the cell resistance are not disturbed by the adjustments made to control the cooling [53].

Electricity consumption figures for large installations for the production of sodium by molten salt electrolysis are given in [54]. The consumption of electrical energy for the electrolysis is 9.8 – 10.5 kWh/kg pure sodium, depending on the length of time that the cell has been in operation. If the associated equipment (ventilation, heating of vessels, and equipment) is included, this increases to 11.5 – 12.0 kWh/kg pure sodium. If a plant for purifying the raw salt and a plant for the purification and liquefaction of the chlorine produced is taken into account, the total energy consumption is 12.0 – 13.0 kWh/kg pure sodium.

4.2.3. Properties of the Electrolyte

The electrolyte consists of a mixture of NaCl, $CaCl_2$, and $BaCl_2$. Some properties of these salts are listed in Table 1.

The melting point of the ternary eutectic of these salts is 450 °C. However, the eutectic mixture is not suitable as a working electrolyte since the $CaCl_2$ content of ca. 50 wt % would result in an unacceptably high proportion of calcium in the sodium product. A mixture of 28 wt % NaCl, 25 wt % $CaCl_2$, and 47 wt % $BaCl_2$ (51 mol % NaCl, 24 mol % $CaCl_2$, 25 mol % $BaCl_2$) is suitable. This mixture melts at 570 °C, and the calcium content of the sodium produced is ca. 1 wt %.

If the rate of sodium chloride addition varies during electrolysis, the NaCl content of the mixture and its melting point fluctuate, but the $BaCl_2$ – $CaCl_2$ weight ratio remains practically constant at 1.88. For example, melting points of the mixture are 550 °C for 26 wt % NaCl and 600 °C for 32 wt % NaCl.

The current efficiency would be 100 % if pure sodium were deposited at the cathode, and no

Table 1. Physical properties of salts used in the Downs cell

Property	NaCl	$CaCl_2$	$BaCl_2$
M_r	58.45	110.99	208.27
Melting point, °C	801	782	963
Density of molten salt at *mp*, g/cm^3	1.6	2.1	3.2
Electrical conductivity of the molten salt at *mp*, Ω^{-1} cm^{-1}	3.6	2.0	2.0

back reaction of sodium with chlorine occurred to form sodium chloride. The diaphragm prevents sodium droplets formed at the cathodes from reacting with the chlorine bubbles formed at the anodes.

However, another possible mechanism for the back reaction, associated with the slight solubility of sodium in the melt, causes the melt to become a partial electronic conductor [55]. The dissolved sodium dissociates into sodium ions and electrons [56]. The electrons and surrounding cations form color centers, called F- centers, that impart a bluish appearance to the melt.

If dissolved sodium is present in the cathode compartment, electrons migrate in the electric field from the cathode across the diaphragm where they react with sodium ions to form sodium. This sodium recombines with the gaseous chlorine present in the anode compartment, which decreases the current efficiency.

To remove dissolved metal (mainly sodium) from the electrolyte, two methods of regeneration have been proposed. In both of these, regeneration of the melt takes place outside the cell. The melt can be melted repeatedly and allowed to solidify, so that the dissolved metals coagulate and separate from the salt melt [57], or the dissolved metals can be oxidized by passing air through the salt melt [58].

Under some circumstances (e.g., during a plant shutdown), the sodium production rate of a cell may have to be reduced for a period of time without interrupting the ohmic resistance heating of the cell. To achieve this, 0.1 – 0.5 wt % aluminum oxide can be added to the melt [59]. Solid bridges of aluminum form between the cathode and the diaphragm, and the latter starts functioning as the cathode. Recombination of sodium with chlorine is no longer prevented and the current efficiency is drastically decreased. Since the melting point of aluminum (660 °C) is above the operating temperature of the cell the aluminum bridges do not melt. To restore the current efficiency to its normal value, the bridges are broken by shaking the diaphragm or replacing it.

4.2.4. Other Electrolytic Processes

Sodium can be deposited electrolytically on a molten lead or mercury cathode to form an alloy [31]. Using this principle, Ashcroft has designed a double cell, in whose primary cell an amalgam is formed by electrolysis of aqueous NaCl with a mercury cathode. Alternatively, molten sodium chloride is electrolyzed with a molten lead cathode. The alkali-metal alloy is then transferred to the secondary cell where the molten salt electrolyte (*mp* ca. 200 °C) is $NaNH_2$, NaCN, or an NaOH – KOH mixture. In the secondary cell, the alloy is anodically decomposed into its constituents, whereby the alkali metal is deposited on the cathode and the alloying metal is returned to the primary cell. However, the Ashcroft process could not compete with other electrolytic processes.

In the Szechtman process, a sodium – lead alloy is produced by electrolysis of molten sodium chloride with a molten lead cathode. The sodium is then recovered from the alloy formed by distillation [31].

Sodium can be recovered by electrolysis of the amalgam produced in the chlor-alkali electrolysis process. Several electrolytic methods have been developed for recovering sodium from the amalgam, but they have not been used commercially (e.g., the Tekkosha process [10, vol. 17, p. 151]).

Reference [60] describes the use of a solid ceramic that conducts sodium ions (as used in the sodium – sulfur battery) as a divider for a two- compartment cell. This method allows low-melting sodium salts or salt mixtures to be used to produce sodium [1, vol. 21, p. 193], [60–64]. This type of cell should give current efficien-

cies approaching 100 % with 30 % lower energy consumption, as well as producing high-purity sodium. The process has, however, not been operated on a large scale [1].

5. Safety

If appropriate regulations and special safety precautions are observed, sodium can be handled safely in inert systems or even in the open air, provided its temperature is <115 °C [11]. The possibility of leakage from pipework and vessels containing molten sodium must be guarded against, because spontaneous ignition can occur at >115 °C [65]. Effectively fighting sodium fires requires a detailed knowledge of the combustion properties of sodium [66]:

1) In sodium fires in vessels in the open air, the temperature in the reaction zone is 900 – 1000 °C. Even in unfavorable conditions, the temperature of the sodium remains below its boiling point. Hence, high rates of combustion, such as those observed with boiling liquids, do not occur with sodium.
2) For any equipment carrying molten sodium, a special system of containment must be provided that safely retains sodium escaping from a leak and effectively prevents contact with air so that a fire cannot develop.
3) The preferred material for insulating sodium- carrying pipework and vessels is rock wool or slag wool with a low content of free silica. For higher temperature, ceramic fibers are suitable. Fibrous insulation made from molten materials is less hygroscopic than powdered or foamed porous material and is therefore preferable. The action of burning sodium on concrete has been studied in detail [67], [68].

The question of an optimum extinguishing agent has been discussed in the literature. The provision of inert-gas atmospheres such as nitrogen or argon in areas at risk from fire is generally too expensive. For pure sodium fires, which take place at the surface, a special expanded graphite is a very suitable fire-fighting material [69]. This powder floats on liquid sodium and thus prevents access of oxygen. Other powders, however, sink in the sodium and hence fail to provide a covering layer. The amount of such powder used on a vessel of molten sodium must therefore always be sufficient to absorb all the sodium and shield it against air [66]. To extinguish small spillages of sodium that have caught fire, powders specially developed and permitted for metal fires (Class D fires), as well as dry salt, dry sand, and anhydrous sodium carbonate, are suitable [11]. Water, foam, halons, CO_2, and fire-extinguishing powders of Classes A, B, and C must not be used under any circumstances [11].

Sodium burns to form sodium oxide (Na_2O) and sodium peroxide (Na_2O_2). With surface fires, 10 – 30 % of the sodium forms an atmospheric aerosol with a typical particle size of 0.001 – 0.002 mm. They combine with atmospheric moisture within a few seconds to form sodium hydroxide. This is followed by reaction with carbon dioxide to form sodium carbonate or hydrogencarbonate, which takes about 3 – 5 min [70–72].

To clean equipment contaminated with sodium, the sodium- containing residues are first removed mechanically and then disposed of (e.g., by controlled combustion). The remaining sodium can then be converted into hydroxide by steam. The excess steam renders the reaction zone inert [11]. The removal of sodium by melting and cleaning out with steam and an alcohol – water mixture (isopropanol with 5 % water) is described in [73]. Small amounts of sodium in the laboratory can be converted to alkoxides, first with isopropanol, then with ethanol, and finally with methanol. Only when hydrogen evolution has ceased should the solution be treated with water. Very small amounts of sodium can be disposed of by storage under paraffin oil in an open beaker, which results in gradual conversion to the hydroxide.

6. Uses

Sodium Compounds. Some sodium compounds are important because of their nucleophilic properties.

Sodium hydride [74] is produced from sodium and hydrogen at 200 – 350 °C (→ Hydrides, Chap. 2.3.). Large quantities are reacted with trimethyl borate to form sodium borohydride

$$4\,NaH + B(OCH_3)_3 \longrightarrow NaBH_4 + 3\,NaOCH_3$$

which is a very good hydrogenation and reducing agent (→ Hydrides, Chap. 3.4.). Its reducing power can be controlled by selection of the solvent and by adding ionic compounds (→ Reduction). Sodium hydride reacts with the following compounds to give their sodium salts [108]: alcohols, phenols, thiols, amines, ketones, alkynes, and carboxylic acids.

Sodium amide (→ Sodium Amide) [74], which is produced from sodium and ammonia, is used mainly to synthesize indigo by the Heumann – Pfleger reaction and to produce sodium azide for the explosives industry. In the Heumann – Pfleger indigo synthesis, sodium amide is used to cyclize phenylglycine, forming indoxyl in very high yield [12], [74]. The reaction is carried out in molten sodium amide at 180 – 200 °C.

Sodium azide is synthesized by reacting molten sodium amide with dinitrogen oxide:

$$N_2O + 2\,NaNH_2 \longrightarrow NaN_3 + NaOH + NH_3$$

On an industrial scale, liquid ammonia is used as a solvent. In a variation of the method, sodium and ammonia are used without isolating $NaNH_2$ [9]:

$$3\,N_2O + 4\,Na + NH_3 \longrightarrow NaN_3 + 3\,NaOH + 2\,N_2$$

Sodium alkoxides [74] are used for *C*-, *N*-, and *O*-alkylation reactions (e.g., of malonic esters, acetoacetic esters, cyanoacetic esters, and benzyl nitrile) and in ring-closure reactions to form nitrogen-containing heterocycles. Alkoxides are used as synthetic building blocks in the Williamson ether synthesis.

Organometallic Compounds. The production of organometallic compounds is an important use of sodium. Organometallic compounds of group IV B metals can be prepared by a modified Wurtz synthesis [74].

Organotin compounds can be produced by the reaction

$$8\,Na + SnCl_4 + 4\,RCl \longrightarrow SnR_4 + 8\,NaCl$$

which, however, is used less often than other methods. Tributyltin oxide is an effective wood preservative:

$$SnCl_4 + 6\,Na + 3\,C_4H_9Cl \longrightarrow (C_4H_9)_3SnCl + 6\,NaCl$$

$$2\,(C_4H_9)_3SnCl + H_2O \longrightarrow (C_4H_9)_3Sn{-}O{-}Sn(C_4H_9)_3 + 2\,HCl$$

Tetraethyllead, $PbEt_4$, is produced by reacting a sodium – lead alloy with chloroethane (→ Lead Compounds, Chap. 3.). Use of the antiknock agents [75] $PbEt_4$ and $PbMe_4$ is being increasingly restricted as a result of environmental legislation.

Synthesis of Vitamin A. The preferred method for the production of vitamin A involves the Wittig reaction, i.e., the reaction of methylenetriphenylphosphorane with benzophenone to give triphenylphosphine oxide and 1,1-diphenylethylene [76]. (→ Sodium Amide, Chap. 5.) Triphenylphosphine is produced from chlorobenzene, sodium, and phosphorus trichloride [76].

$$3\,C_6H_5Cl + 6\,Na + PCl_3 \longrightarrow (C_6H_5)_3P + 6\,NaCl$$

Since the expensive triphenylphosphine is irreversibly converted to triphenylphosphine oxide in the Wittig reaction, ways have been sought to reuse the latter. An economic process has been developed in which the phosphine oxide is reacted with phosgene to give the dichloride, which is coproportionated with phosphorus [76].

$$(C_6H_5)_3P{=}O + COCl_2 \xrightarrow{-CO_2} (C_6H_5)_3PCl_2$$

$$3\,(C_6H_5)_3PCl + 2\,P \longrightarrow 3\,(C_6H_5)_3P + 2\,PCl_3$$

Metallurgy. Metals such as titanium, zirconium, tantalum, hafnium, and niobium can be produced in high purity by reacting their chlorides with sodium. Pure titanium was first prepared in 1887 by two Swedish chemists, using the reaction

$$TiCl_4 + 4\,Na \longrightarrow Ti + 4\,NaCl$$

This method of preparation became known as the Hunter process. The reaction of sodium with titanium tetrachloride is usually carried out by placing the two reactants in an evacuated steel bomb and initiating the reaction by passing an electric current through a wire. Other methods of production are now available (e.g., a process involving direct electrolysis of titanium tetrachloride).

Small amounts of sodium are used in lead refining, for optimizing aluminum – silicon melts and improving the properties of bronzes [11]. Sodium treatment [77] of Al – Si melts prevents anomalous crystallization, characterized by the precipitation of needle-like or lamellar silicon [78–80]. Sodium leads to supercooling processes [81], [82] that result in rounded eutectic silicon, normal fine eutectic solidification, and improved material properties, especially tensile properties [83].

Sodium – Sulfur Batteries. Rechargeable batteries with liquid sodium as the anode, sulfur – sodium polysulfide as the cathode, and sodium-doped aluminum oxide as the solid electrolyte are available for testing in the automobile industry [5], [84].

The two active materials, sodium and sodium polysulfide, are separated by a solid electrolyte of β-aluminum oxide, which conducts sodium ions. The operating temperature of the battery is 300 – 350 °C [85]. The most important component of a sodium – sulfur cell is the tube of solid electrolyte that separates the two molten electrodes. This material must be highly permeable to sodium ions and have a long lifetime to give a sodium – sulfur battery with a high power density and long working life [86].

Sodium as a Heat-Transfer Medium. The alkali metals, particularly sodium, were first used on a large scale as heat-transfer media by the nuclear energy industry. Liquid sodium is used worldwide as a coolant in fast breeder reactors (→ Nuclear Technology, Chap. 4.1.2.). Power stations may contain several thousand tonnes of the metal. Both its nuclear properties and its very favorable thermal properties have led to the choice of sodium to cool fast breeder reactor cores, where the heat flux is high. Alkali metals are also used to a limited extent as heat-transfer media outside the nuclear industry [87]. In a solar energy plant in the Mojave Desert, California, sodium is used to store energy and transfer it from the collector to the steam generator [88].

7. Sodium Alloys

According to Mott's rule [89], the miscibility of alkali metals with other metals in the liquid state depends on the ratios of the atomic radii, vapor pressures, and electronegativities of the dissolved metal and the solvent metal. Furthermore [8], the interaction of alkali metals with elements of group A (*s*- and *p*-block) of the periodic table differs from their interactions with the elements of group B (*d*- and *f*-block). Many elements of group A form intermetallic compounds with the alkali metals, unlike the elements of group B, which interact to a much lesser extent. The transition metals, including lanthanides and actinides, have very low solubilities in molten alkali metals. The metals of groups I B (Cu, Ag, and Au) and II B (Zn, Cd, and Hg) and the platinum-group metals are exceptions to this. In group I B, the solubility increases from copper to gold, the very low solubility of copper being similar to that of the transition metals.

Few of the many sodium alloys are of industrial importance. Some are briefly described below [90].

Sodium – potassium alloys [91] are used mainly in heat exchange systems, because of their good thermal conductivity and the wide temperature range over which they are liquid. The physical properties of two typical Na – K alloys are listed in Table 2. A review of physical properties and chemical reactions is given in [13]. Large-scale production is described in [5]. The ternary alloy, 12 wt % Na, 47 wt % K, and 41 wt % Cs, has the lowest known melting point (−78 °C) of all metallic systems [9].

Table 2. Physical properties of Na – K alloys [8]

Property	Composition, wt % K	
	44	78
Melting point, K	292.15	260.48
Boiling point, K	1098.15	1057.15
Density, kg/m^3 (373.15 K)	886	847
Viscosity, mPa · s (523 K)	0.316	0.279
Heat capacity, kJ kg^{-1} K^{-1} (473 K)	1.096	1.045
Thermal conductivity, W m^{-1} K^{-1} (473 K)	26.36	25.10

Although Na and K are chemically similar and both form face-centered cubic structures, the difference in atomic radii >15 %. The two are immiscible (i.e., no mixed-crystal formation occurs [92]). The compound KNa_2 is a so-called Laves phase, in which mixed-crystal formation is impossible because the difference in radius is too large [93].

Sodium – calcium alloys are byproducts of the molten salt electrolytic production of sodium from the binary salt mixture $NaCl - CaCl_2$ and the ternary mixture $NaCl - CaCl_2 - BaCl_2$. Calcium is only partially miscible with sodium. Calcium – sodium alloys containing 25 – 65 wt % sodium can be separated by high-temperature vacuum distillation [13]. Figure 6 shows the sodium – calcium phase diagram [94].

Sodium – Lead Alloys. Various methods have been described for the production of sodium – lead alloys because of their importance in the production of alkyl lead compounds [13]. One possibility is to melt the two metals together. Another is to deposit sodium electrolytically on molten lead cathodes [10]. Sodium and lead are completely miscible in the liquid state above 400 °C [13]. The following sodium – lead compounds are known.: $NaPb_3$, NaPb, Na_9Pb_4, Na_5Pb_2, and $Na_{15}Pb_4$ [95].

Sodium Alloys with the Coinage Metals. Copper has very low solubility in sodium [91], and no sodium – copper compounds have been reported. Although copper is resistant to sodium up to 300 – 400 °C, it is not recommended as a construction material for vessels or pipes containing sodium [13].

Silver has limited solubility in sodium [13], [91]. The existence of the compound $NaAg_2$ has been reported.

With gold, sodium forms the compound $NaAu_2$ (*mp* 1005 °C), which is the most stable compound in the Na – Au system [95]. It can be prepared from gold powder and sodium at 250 °C under high vacuum [13]. Sodium – gold alloys exhibit photoelectric properties and can be used in photocells [10].

Sodium Alloys with Group II B Metals. Zinc, cadmium, and mercury are very soluble in alkali metals [91]. The solubility in sodium increases from zinc to cadmium. The compounds $NaZn_{13}$ and $NaCd_2$ have been reported [91], [95]. Sodium and mercury form the following intermetallic compounds: $NaHg_4$, $NaHg_2$, Na_7Hg_8, NaHg, Na_3Hg_2, Na_5Hg_2, and Na_3Hg [95], [96]. A liquid amalgam containing ca. 1 % sodium is an intermediate product in chlor-alkali electrolysis and is used to produce sodium hydroxide solution. Amalgams with higher sodium content (1.25 %) are viscous liquids. Still higher sodium contents result in silvery-white crystalline solids [10]. The physical properties, chemical reactions, and production of sodium amalgam are described in [13].

Many attempts have been made to utilize the reducing properties of sodium amalgam in chemical syntheses [97]. Sodium dithionite is produced on a large scale by the reduction of SO_2 with sodium amalgam. Other uses of sodium amalgam include the production of sodium sulfide, reduction of salicylic acid to salicylaldehyde, and reduction of nitrobenzene to azobenzene. These reactions are no longer of industrial importance. The reaction of sodium amalgam with alcohols in a vessel filled with graphite spheres to form alkoxides is used to a limited extent [97].

Sodium amalgam formation can be used to recover mercury from mercury-containing but-

Figure 6. Calcium – sodium phase diagram [94]

ton cells. After treatment with molten sodium, the nonextractable solids are removed, and the amalgam is decomposed electrolytically into its constituents with a solid electrolyte made of sodium-ion- conducting β-Al_2O_3 [98].

8. Packaging and Transport

8.1. Forming Sodium Metal

Alkali metals are often marketed in shaped pieces of various sizes and weights. However, sodium is supplied to the customer mainly in the form of cast blocks produced by pouring the molten metal into containers and allowing it to cool and solidify. The shaped pieces are produced primarily by melting and casting the liquid metal. Alkali metals, especially sodium, are also pressed into variously shaped billets while in the solid state. The most serious disadvantage of these processes is the formation of impurities by reaction of the metal with air and atmospheric moisture. Also, the high pressure required for pressing the solid metal leads to wear. Pressing solid alkali metals is always a batch operation. The output of the machine is therefore limited, and the labor costs are high compared to a continuous process.

The production of alkali metal billets by continuous casting under pressure has also been described. In the presence of a lubricant the molten metal is forced by a pump through a die cooled to below the melting point of sodium [99].

In the extrusion molding process described in [100], molten metal is charged batchwise into the so- called feeder and, after cooling, until it is in a hot plastic state, is formed into an ingot, which is then extruded to form a billet by means of a plunger.

In the technique described in [101], two separate sets of machinery are used for extrusion of the alkali metal. The molten metal is fed into a gear pump, which delivers liquid metal. In a cooler, which is separate from the pump, the liquid alkali metal is cooled below its melting point and pressed into a solid shape under pressure from the gear pump (ca. 15 MPa).

In a state-of-the-art process [102], liquid alkali metal is fed into a twin-screw extruder, which is cooled such that the temperature falls to slightly below the melting point of the metal just before the extrusion die. The alkali metal is thus solid but sufficiently ductile for extrusion. The extrusion pressure at the outlet is 3 – 5 MPa.

The alkali-metal billet produced can be cut by an automatic cutting device, sometimes under a protective gas, to produce lengths suitable

Figure 7. Schematic of an extrusion plant for the production of alkali-metal billets [102]
a) Sodium storage tank, heated; b) Drive; c) Sealing layer of sodium; d) Feeding nozzle; e) Twin-screw extruder; f) Heating and cooling jacket; g) Extrusion die; h) Cutting machine

for packing. Figure 7 shows a schematic of an extrusion plant for the production of alkali-metal billets [102].

After manufacture, sodium is in the molten state and can be filled immediately into freight containers. The following types are available:

1) Rail tank cars with a capacity of up to 45 t sodium
2) Road tank vehicles with a capacity of up to 20 t sodium
3) Iso-containers with a capacity of up to 20 t sodium
4) Special containers with a net capacity of up to 5 t sodium, and smaller packaging units in the form of drums of various types

Sodium is usually transported in the solid state for safety reasons and therefore must be remelted before it is emptied from the containers. This method of shipment allows the metal to be delivered in a very pure form. However, special handling equipment at the unloading site is required.

8.2. Transport Regulations

Sodium metal is a Class 4.3 hazardous material for all kinds of transport [103]. Detailed transport classifications read:

Road and Rail (Europe), ADR/RID: Class 4.3, No. 11 a
Inland Waterways (Europe), ADNR and ADN: Class 4.3, No. 11 a
Sea Cargo (Worldwide), IMDG Code: Class 4.3, UN No. 1428, PG. I
Air Cargo (Worldwide), ICAO-T I and IATA-DGR: Class 4.3, UN No. 1428, PG. I

The European transport regulations were harmonized with the UN-recommendation-based regulations for sea and air transport of January 1, 1993. Thus sodium metal may be transported worldwide by using a unified packing system. However, different weight limits and packaging requirements are specified for various methods of transport.

8.3. Break-Bulk Packaging

For all kinds of transport UN-approved PG. I packaging has to be used. PG. I means the highest test standard for performance-oriented packaging. The packaging must have no venting device.

Road and Rail Transport in Europe. Sodium metal must be hermetically sealed, so that neither moisture nor any other substance can penetrate the packaging and come in contact with the contents. The provision to cover the sodium with an inert gas or protective liquid is no longer required.

The following types of packaging are permitted: single packaging such as drums and canisters with removable head (made of steel or plastic) with a maximum capacity of 450 L or a net weight of 400 kg, as well as combination packaging (such as glass containers of 5-kg capacity, plastic containers of 30-kg capacity, or metal containers of 40-kg capacity) inside outer packages such as wooden, cardboard, or metal boxes with a maximum permissible net weight of 400 kg.

European Inland Waterways. Packaging regulations for European inland waters are identical with those for road and rail transport.

Sea Transport. In contrast to land transport, a distinction is made between lumps and solid fused goods (i.e., those poured into the container in a molten state) in sea transport.

Lumps have to be packed in hermetically-sealed (vapor-tight closure) packaging and must be completely covered by a protective liquid (flash point $> 50\,^{\circ}$C) or covered with nitrogen. The following types of packaging are permitted: Steel drums with removable head with a maximum net weight of 250 kg, or combination packaging such as glass bottles (max. 1 kg gross) packed in wooden boxes (max. 5 kg gross), metal boxes or cans (max. 15 kg net) packed in wooden boxes (max. 115 kg gross), or cardboard boxes (max. 40 kg gross).

Solid fused sodium must be packed in effectively closed (liquid-tight closure) drums with removable head with a maximum net weight of 250 kg.

Air Transport. Sodium metal may be transported only by cargo aircraft; transport by passenger aircraft is not permitted. The net weight per package must not exceed 50 kg. Special conditions and permitted types of packing are described in packing instruction No. 418 of the air transport regulations ICAO-T I/IATA-DGR[12].

8.4. Portable Tanks

Portable tanks include rail tank cars, road tank vehicles, and demountable tanks. Rail tank cars have a capacity up to ca. 45 t; tank containers and road tanker trucks, up to ca. 25 t.

Tanks for transporting sodium metal must be tested to a minimum pressure of 0.4 MPa. The temperature on the tank shell must not exceed 70 °C during transportation. Insulating material must be nonflammable. The atmosphere inside the tank must be inerted by an inert gas.

Road and Rail Transport in Europe. Although the transport of molten sodium metal is allowed, many producers allow the fused sodium to solidify the outer layer, so that escape of liquid sodium is prevented in case of leakage. Openings below the surface level of the material are permitted.

Portable tanks for sodium metal must undergo testing at eight-year intervals after the first certification, including testing of the condition of the inside and outside of the vessel and pressure testing with a liquid. In addition, a leakproofness test of the tank with its equipment and a check of the satisfactory operation of the equipment must be carried out at least at four-year intervals.

Transport by European Inland Waterways. Regulations for inland waterways are identical with those for the road and rail transport of movable large containers.

Sea Transport. IMO tank type 1 containers with a minimum wall thickness of 6 mm and a minimum test pressure of 0.4 MPa must be used. IMO tank type 1 tanks have a capacity of $>$450 L, with a maximum permitted operating pressure of 175 kPa or above. Road tank vehicles and rail tank cars used to transport sodium

on seagoing vessels have to comply with the IMO tank type 1 provisions too. In contrast to the land transport regulations, the sea transport regulations do not permit openings below the surface level to the material, i.e., the tank must be equipped with top openings. For sea transport, the sodium metal must be in the solid state.

Table 3. Trace impurities in sodium: Typical analysis figures and methods of determination [11]

Element	Concentration, ppm	Methods of determination
Aluminum	0.5	AAS, Zeeman
Arsenic	<1	AAS, Zeeman
Barium	<5	AAS, Zeeman
Boron	<1	Photometric
Calcium∗	450	Titrimetric
Calcium∗	5	AAS
Carbon	2	Dissolve, filter, GC
Carbon∗∗	7	Vacuum distill, GC
Chlorine	4	Nephelometry
Chromium	<0.5	AAS, Zeeman
Cobalt	<0.5	AAS, Zeeman
Copper	<0.5	AAS, Zeeman
Iron	4	AAS, Zeeman
Lead	<0.5	AAS, Zeeman
Lithium	<1	AAS
Magnesium	<1	AAS, Zeeman
Nickel	<0.5	AAS, Zeeman
Oxygen∗∗	7	Amalgam process, AAS
Phosphorus	<0.5	Photometric
Potassium	70	AAS
Silicon	<1	AAS, Zeeman
Silver	<1	AAS, Zeeman
Strontium	5	AAS, Zeeman
Sulfur	<4	AAS
Tin	<1	AAS, Zeeman
Zinc	0.3	AAS, Zeeman

∗ Specification: normal grade <600 ppm, nuclear grade <10 ppm.
∗∗ Owing to the high affinity of sodium for atmospheric oxygen, moisture, and carbon dioxide (formation of oxides, hydroxide, and carbonate), the figures given apply only to sodium that has come in contact with dry inert gas atmospheres (O_2 <1 ppm, H_2O <1 ppm) during filling, storage, and handling.

9. Quality Specifications and Analysis

Sodium is marketed with a purity of >99 wt %. Depending on the production method, standard-quality sodium can contain between 400 and 600 ppm of calcium [11]. Purification of sodium is described in [8].

Methods based on filtration and cooling depend on the low solubility of many elements in liquid sodium just above its melting point. Impurities remain in the filtration residue or settle out in solid form in cool traps.

The affinity of some of the impurities in sodium for oxygen is also utilized in purification processes since the oxides formed are easily removed from the sodium. For example, calcium is reacted with Na_2O or Na_2O_2 at 300 – 400 °C, and the calcium oxide formed is filtered off [5], [104].

The trace elements in sodium are listed in Table 3, with typical analysis figures and analytical methods [11]. Sodium can also be obtained in special grades [105].

10. Health and Safety

Sodium can be handled safely without endangering the health of personnel concerned, provided appropriate precautions are taken to deal with possible hazards [106]:

1) Spontaneous ignition of sodium in moist air at >115 °C
2) Severe caustic effects of the combustion products of sodium
3) Fire explosion associated with uncontrolled chemical reaction between sodium and acid, water, aqueous solutions, alcohol

Sodium must always be stored, transported, and handled under dry and inert conditions. Direct contact with the skin must be prevented by wearing gloves and clothing made of flame-resistant material. The eyes are protected by spectacles, goggles, or shields in all circumstances.

Information and advice about necessary technical, organizational, and personal protective measures can be obtained from company publications [11], [107] and leaflets available from chemical industrial trade associations [106]. Methods for safe working with sodium in the laboratory are described in detail in [8], [11].

11. Economic Aspects

Until recently, sodium was used mainly for the production of lead- containing antiknock agents for gasoline and for the production of titanium. However, the increasing use of lead-free gasoline and the manufacture of titanium by

other processes have led to a drastic reduction in sodium capacity worldwide [108], [109]. In 1979, world sodium capacity, excluding the former Eastern-bloc states, was estimated at 250 000 t/a [10]. By 1986, this had decreased to 200 000 t/a [5]. In 1993 it is expected to be ca. 80 000 t/a. The most important sodium producers in the Western world, with their 1993 capacities are listed below:

Du Pont, Niagara Falls, United States	51 000 t/a
Associated Octel, Ellesmere Port, United Kingdom	20 000 t/a
Métaux Spéciaux, Pomblière, France	12 000 t/a

1. Sodium Carbonate

1.1. Introduction

Sodium carbonate (soda ash) is the neutral sodium salt of carbonic acid. It is one of the most important raw materials used in the chemical industry, and has been known by humans since ancient times. Sodium carbonate had many uses even then (cleaning and glass manufacture) for which it is still indispensable. Sodium carbonate from the deposits in Wadi Natrun (4 % Na_2CO_3, 25 % $NaHCO_3$) was traded in ancient Egypt.

Production of the alkaline materials sodium carbonate and potassium carbonate (which were recognized rather late as chemically distinct) was carried out from ancient times until the 1800s by the combustion of marine and land vegetation, followed by calcination at red heat and leaching of the ash. The term soda ash originates from this process.

The soda ash obtained in this way was a low-percentage material; e.g., Spanish barilla contained 25 – 30 % Na_2CO_3, varec from Normandy 3 – 8 %, and Scottish kelp 10 – 15 %. The soda ash produced from plants was very expensive, and the processes used were too primitive for mass production and consumed vast quantities of vegetation.

Large-scale production was possible only after the development of a new process, named after its inventor LEBLANC (1742 – 1806). In 1790, the first plant was built in Saint-Denis, France. Initially, production was 300 kg/d. In the following years, the soda industry developed rapidly in England due to the increasing demand for soda ash to clean cotton from the colonies. In 1878, production in England was 8 t per week, and in the rest of the world, 4 t a week.

However, in the second half of the 1800s, the Leblanc soda ash process experienced serious competition from the Solvay process. In the first half of the 1800s, investigations were already being carried out into the industrial use of the double decomposition reaction of NaCl with NH_4HCO_3, but without success. However, the Belgian ERNEST SOLVAY (1838 – 1932) brought the development of the process to a successful conclusion during 1861 – 1865. The first plant was started up in 1865 in Couillet, Belgium, with an initial production of 1.5 t/d. The first Solvay plant in Germany was built in 1880 in Wyhlen on the upper Rhine.

The technically and economically superior Solvay process displaced the Leblanc to such an extent that by the early 1900s only a few Leblanc plants were in production. The last Leblanc works ceased operation around 1923. Since

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_299

then, the Solvay process has remained predominant. Since World War II, soda ash has been increasingly obtained from trona, especially in the United States (see Section 1.4.3).

1.2. Properties

Physical Properties. In addition to anhydrous sodium carbonate, Na_2CO_3, the following hydrates exist: sodium carbonate monohydrate, $Na_2CO_3 \cdot H_2O$; sodium carbonate heptahydrate, $Na_2CO_3 \cdot 7\,H_2O$; and sodium carbonate decahydrate, $Na_2CO_3 \cdot 10\,H_2O$. The physical properties of these compounds are listed in Table 1. Solubilities of the hydrates of sodium carbonate are shown in Figure 1. The relationship between the concentration of an aqueous solution of Na_2CO_3 and its pH at 25 °C is shown in Figure 2.

Figure 1. Solubilities in the system $Na_2CO_3 - H_2O$ [1] Temperatures and concentrations of the two-salt points and the cryohydric point

Chemical Properties. *Thermal Behavior.* The thermal decomposition of sodium carbonate to sodium oxide and carbon dioxide in a vacuum in the absence of chemically activating substances such as water vapor begins at ca. 1000 °C. The dissociation pressure is ca. 200 Pa and increases to 10.3 kPa at 1450 °C [3].

Reaction with Water and Carbon Dioxide. Sodium carbonate is hygroscopic. In air at 96 % R.H. its weight can increase by 1.5 % within 30 min [4].

Figure 2. pH values of aqueous solutions of Na_2CO_3 at 25 °C [2]

Concentration, g Na_2CO_3/100 g solution	0.0055	0.0217	0.0884	0.2246
pH at 25 °C	10.274	10.612	10.919	11.063
Concentration, g Na_2CO_3/100 g solution	0.4376	0.8609	1.806	4.241
pH at 25 °C	11.171	11.254	11.357	11.453
Concentration, Concentration, Na_2CO_3/100 g solution	12.034	18.555		
pH at 25 °C	11.617	11.699		

If sodium carbonate is stored under moist conditions, its alkalinity decreases due to absorption of moisture and carbon dioxide from the atmosphere

$$Na_2CO_3 + H_2O + CO_2 \longrightarrow 2\,NaHCO_3$$

Water vapor reacts with sodium carbonate above ca. 400 °C to form sodium hydroxide and carbon dioxide [5].

Reaction with Elements. Sodium carbonate reacts exothermically with chlorine above ca. 150 °C to form NaCl, CO_2, O_2, and $NaClO_4$ [6].

The elements platinum, gold, vanadium, titanium, zirconium, aluminum, molybdenum, tungsten, and iron (1200 °C) are attacked by fused Na_2CO_3, with liberation of CO_2 and formation of complex metal oxide – sodium oxide compounds. At higher temperature, the Na_2O formed reacts with excess metal to form sodium metal vapor [7]. Sodium carbonate reacts very

Table 1. Physical properties of sodium carboante and its hydrates

	Anhydrous	Monohydrate	Heptahydrate	Decahydrate
Formula	Na_2CO_3	$Na_2CO_3 \cdot H_2O$	$Na_2CO_3 \cdot 7\,H_2O$	$Na_2CO_3 \cdot 10\,H_2O$

slowly with copper and nickel at high temperature (> 1500 °C).

1.3. Sodium Carbonate Minerals

Whereas the production of sodium carbonate from the ashes of plants that grow in salty soil near the sea is only of historical interest, extraction from soda-containing minerals, especially trona, is of increasing importance.

The most important deposits are located in Wyoming (Green River District), California (Owens Lake and Searles Lake), East Africa (Magadi Lake), and Lower Egypt (Wadi Natrun).

The proportion of Na_2CO_3 in the salt mixture in such deposits seldom exceeds 40 %. The accompanying compounds include sodium hydrogencarbonate, borax, sodium sulfate, sodium chloride, and potassium chloride.

For example, the concentrations of dissolved salts in the water of Owens Lake are [8]

9 % Na_2CO_3	1 % $Na_2B_4O_7$	16 % NaCl
1.2 % $NaHCO_3$	3 % Na_2SO_4	1.5 % KCl

Deposits of Na_2CO_3-containing minerals occur worldwide:

Trona	$Na_2CO_3 \cdot NaHCO_3 \cdot 2\,H_2O$
Natron	$Na_2CO_3 \cdot 10\,H_2O$
Thermonantrite	$Na_2CO_3 \cdot H_2O$
Hanksite	$2\,Na_2CO_3 \cdot 9\,Na_2SO_4 \cdot KCl$
Pirssonite	$Na_2CO_3 \cdot CaCO_3 \cdot 2\,H_2O$
Gaylussite	$Na_2CO_3 \cdot CaCO_3 \cdot 5\,H_2O$

Only trona is of commercial importance. These Na_2CO_3-containing minerals were formed from the original rock by the erosive action of air, water, heat, and pressure, followed by chemical changes caused by the action of atmospheric carbon dioxide. The carbonate-containing salts formed were leached by water and then concentrated and crystallized by evaporation.

1.4. Production

1.4.1. Ammonia – Soda Process

1.4.1.1. General and Theoretical Principles

The ammonia – soda process is based on the formation of sparingly soluble sodium hydrogencarbonate (known in the soda industry as bicarbonate) by reacting sodium chloride with

ammonium hydrogencarbonate in aqueous solution:

$$NaCl + NH_4HCO_3 \rightleftharpoons NaHCO_3 + NH_4Cl$$

The process includes the following stages:

1) Production of a saturated salt solution
   $NaCl + H_2O$
2) Burning of limestone or chalk (the CO_2 liberated is used in stage 4)
   $CaCO_3 \longrightarrow CaO + CO_2$
3) Saturation of the salt solution with ammonia
   $NaCl + H_2O + NH_3$
4) Precipitation of bicarbonate by the introduction of carbon dioxide (from stages 2 and 6)
   $NaCl + H_2O + NH_3 + CO_2$
   $\longrightarrow NH_4Cl + NaHCO_3$
5) Filtering and washing of precipitated bicarbonate
6) Thermal decomposition of bicarbonate to sodium carbonate (the CO_2 evolved is recycled to stage 4)
   $2\,NaHCO_3 \longrightarrow Na_2CO_3 + H_2O + CO_2$
7) Production of milk of lime
   $CaO + H_2O \longrightarrow Ca(OH)_2$
8) Recovery of ammonia by distillation of the mother liquor from stage 4 (bicarbonate precipitation) with milk of lime (the ammonia liberated is recycled to stage 3)
   $2\,NH_4Cl + Ca(OH)_2$
   $\longrightarrow 2\,NH_3 + CaCl_2 + 2\,H_2O$

The liquid remaining after distillation is usually discarded in its entirety, because only a small fraction can be used for calcium chloride production, depending on demand.

The process can be represented by the following simplified equation:

$$2\,NaCl + CaCO_3 \longrightarrow Na_2CO_3 + CaCl_2$$

In aqueous solution, the reaction proceeds from right to left due to the low solubility of calcium carbonate. The role of ammonia is to promote the formation of sodium bicarbonate via the intermediate ammonium bicarbonate.

The reaction that takes place in aqueous solution

$$NaCl + NH_4HCO_3 \rightleftharpoons NaHCO_3 + NH_4Cl$$

is determined by the solubilities of the individual salts in the presence of other components of the reciprocal salt pairs. These solubility relationships have been investigated by FEDOTIEFF [9].

The basic principles can be explained by using the 15 °C isotherm (Fig. 3), based on the values given in Table 2. The figure is the orthogonal projection of a three-dimensional diagram (i.e., a four-sided pyramid whose edges represent the coordinates of NaCl, NH_4Cl, NH_4HCO_3, and $NaHCO_3$). This diagram shows the ranges of existence of the individual solid phases that are in equilibrium with their saturated solutions at 15 °C:

Area a – I – P_2 – II:	NaCl
Area II – P_2 – P_1 – III – b:	NH_4Cl
Area P_1 – III – c – IV:	NH_4HCO_3
Area I – P_2 – P_1 – IV – d:	$NaHCO_3$

Figure 3. The 15 °C isotherm for the reciprocal salt pair $NaCl + NH_4HCO_3$ (concentrations in mol/1000 g H_2O are shown on the ordinate and abscissa)

Along the lines I – P_2, II – P_2, P_2 – P_1, P_1 – III, and P_1 – IV, two solid phases coexist, and at the points P_1 and P_2, three solid phases coexist. These two points are thus monovariant because in the presence of three solid phases, a change in concentration is possible only by changing the temperature.

The point P_1, at which the three salts NH_4Cl, NH_4HCO_3, and $NaHCO_3$ coexist, is of special importance for the ammonia – soda process, because this point has the highest NH_4Cl concen-

Table 2. Reciprocal salt pair $NaCl + NH_4HCO_3 \rightleftharpoons NaHCO_3 + NH_4Cl$ 15 °C isotherm, monovariant points (mol/1000 g H_2O)

Point	NaCl	$NaHCO_3$	NH_4Cl	NH_4HCO_3	Solid phase
a	6.12				NaCl
b			6.64		NH_4Cl
c				2.36	NH_4HCO_3
d		1.05			$NaHCO_3$
I	6.06	0.12			$NaCl + NaHCO_3$
II	4.55		3.72		$NaCl + NH_4Cl$
III			6.40	0.81	$NH_4Cl + NH_4HCO_3$
IV		0.71		2.16	$NaHCO_3 + NH_4HCO_3$
P_1	0.51	0.93	6.28		$NH_4Cl + NH_4HCO_3 + NaHCO_3$
P_2	4.44	0.18	3.73		$NH_4Cl + NaCl + NaHCO_3$

tration in the entire range. If point P_1 is reached by the precipitation of bicarbonate, it represents the maximum attainable sodium yield. Nevertheless, working so that neither the point P_1 nor the lines $P_1 - P_2$ and $P_1 - IV$ are actually reached is advisable, to avoid coprecipitation of $NaHCO_3$, NH_4Cl, or NH_4HCO_3. The coprecipitation of NH_4Cl has a particularly detrimental effect on the quality of the soda, because it is converted to NaCl on calcination:

$$NH_4Cl + NaHCO_3 \longrightarrow NaCl + NH_3 + CO_2 + H_2O$$

or

$$2\,NH_4Cl + Na_2CO_3 \longrightarrow 2\,NaCl + 2\,NH_3 + CO_2 + H_2O$$

An end point that is as close as possible to P_1 but lies within the hatched area in Figure 3 is best.

Figure 4. The 30 °C isotherm for the reciprocal salt pair $NaCl + NH_4HCO_3$
On the ordinate and abscissa of the square diagram, the amount of each salt is shown as a molar fraction of the total salt content of the solution.

The course of bicarbonate precipitation can be followed clearly in the square diagram of JÄNECKE [10]. Figure 4 shows the 30 °C isotherm of the system in such a diagram. This diagram does not represent absolute solubilities, but percentages of salts in the total salt content of the solution. Thus, the corners represent pure salts or solutions of a single salt, and the lines joining two corners represent mixtures of two salts. Points within the square represent mixtures or solutions of three salts. The solubilities can be found from the diagram if the appropriate water value is given for each point of equilibrium (the salt value being 1 kmol in all cases). This can be shown by means of lines of equal water content (isohydric lines).

The points, lines, and areas in Figure 4 have the same significance in principle as those in the 15 °C isotherm diagram of Figure 3. The corner point (a) corresponds to a solution of pure sodium chloride. If NH_4HCO_3 is added (by passing carbon dioxide and ammonia into the solution), the mixture moves from point (a) toward point (c) (NH_4HCO_3). In the case of saturation, systems represented by points on line $m_1 - m_2$ are in equilibrium with $NaHCO_3$ as solid phase.

In the ammonia – soda process, point (a) represents a solution that is not completely saturated (9.7 instead of 9.01 kmol H_2O/kmol NaCl). Point (m_3) on line a – c is reached by the introduction of CO_2 and NH_3 in an equimolar ratio. At this point, the water content necessary to give a saturated solution is ca. 17.5 kmol/kmol dissolved salt (see isohydric lines in Fig. 4). However, the proportion of water introduced with the brine, which is further reduced by the reaction of NH_3 with CO_2 to form NH_4HCO_3, is only ca. 7 kmol/kmol dissolved salt. This leads to the precipitation of sodium bicarbonate.

The precipitation process consists of separation of the supersaturated system (m_3) into the solid pure component $NaHCO_3$ (point d) and the saturated mother liquor (m_4).

Figure 5. Flow sheet of the ammonia–soda process

In the Solvay process the degrees of utilization of Na^+ and NH_4^+ are both important. These can be calculated from the composition of the mother liquor (determined by chemical analysis) by using the equations:

$$U_{Na^+} = \frac{100\ (Cl^- - Na^+)}{Cl^-}$$

$$U_{NH_4^+} = \frac{100\ \left(NH_4^+ - HCO_3^-\right)}{NH_4^+}$$

In these equations, Cl^-, Na^+, NH_4^+, and HCO_3^- denote the concentrations in moles per kilogram of H_2O, and U_{Na^+} and $U_{NH_4^+}$ denote the percentage utilization of Na^+ and NH_4^+. The values for U_{Na^+} and $U_{NH_4^+}$ depend on the starting concentrations, and maximum Na^+ utilization does not correspond to maximum NH_4^+ utilization. These relationships are illustrated by the values given in Table 3.

Table 3. Percentage utilization of Na^+ and NH_4^+ in the reaction of NaCl with NH_4HCO_3 at 15 °C and various initial concentrations

Initial concentration of solution, mol/100 g H_2O		Point	Solution produced, g mol/1000 g H_2O				Utilization, %	
NaCl	NH_4HCO_3		HCO_3^-	Cl^-	Na^+	NH_4^+	Na^+	NH_4^+
8.188	3.730	P_2	0.18	8.188	4.62	3.730	43.58	95.17
7.658	4.552		0.31	7.658	3.39	4.552	55.73	93.19
7.128	5.450	↓	0.51	7.128	2.19	5.450	69.28	90.64
6.786	6.272	P_1	0.92	6.786	1.44	6.272	78.78	85.33
6.000	5.640		0.99	6.000	1.34	5.640	77.67	82.45
5.403	5.210	↓	1.07	5.403	1.27	5.210	76.49	79.46
5.025	4.919		1.12	5.025	1.23	4.919	75.52	77.23
4.000	4.135	IV	1.30	4.000	1.16	4.135	71.00	68.56

For economic operation of the process, the utilization of Na^+ should be high, rather than that of NH_4^+, since unconsumed NH_4^+ is recycled. Therefore, in practice, Na^+ utilization is between 72 and 76 %, and NH_4^+ between 69 and 71 %. However, note that consideration of phase rule theory gives no information about kinetic effects such as rates of reaction, nucleation, and crystallization.

A comprehensive treatment of the phase rule theory is given in [11, pp. 125 – 160].

1.4.1.2. Technology

The Solvay ammonia – soda process is shown schematically in Figure 5. The main operational stages are shown in the numbered bold rectangles:

Stage 1: Brine Purification. The sodium chloride used as a raw material in the Solvay process can be obtained by conventional or solution mining [12].

The brine always contains inorganic impurities that lead to production problems and impair the quality of the final product. For example, calcium and magnesium ions can cause scaling in the equipment and pipework due to the formation of basic carbonates during ammonia absorption, which can seriously interfere with the process. Purification of the brine, which should be as near saturation as possible to achieve optimum Na^+ utilization, is best carried out by the lime – soda process. Magnesium ions are precipitated as hydroxide, and calcium ions as carbonate:

$$Mg^{2+} + Ca(OH)_2 \longrightarrow Mg(OH)_2 + Ca^{2+}$$

$$a^{2+} + Na_2CO_3 \longrightarrow CaCO_3 + 2\,Na^+$$

The reagents used in this precipitation are prepared by dissolving soda ash or milk of lime in brine (Na_2CO_3 concentration: 65 – 80 kg/m^3; $Ca(OH)_2$ concentration: 170 – 185 kg/m^3). Reaction times, crystallization rates, and settling rates are improved if the brine with the added reagent solutions is mixed with a recycled seed slurry. Under these conditions, precipitates of calcium carbonate and magnesium hydroxide can be produced with settling rates up to 1 m/h, and in some cases even 3 m/h.

Stage 2: Limestone Burning and Lime Slaking. The limestone must be of very high purity (SiO_2: < 3 %; $Fe_2O_3 - Al_2O_3$: < 1.5 %). From it, both carbon dioxide for the carbonation stage and calcium oxide for the distillative recovery of ammonia are produced by calcination with coke (see → Lime and Limestone).

The quantity of limestone used per tonne of soda ash produced is determined solely by the amount of calcium oxide required for ammonia recovery. Hence, the excess carbon dioxide is either released to the atmosphere or supplied to other consumers.

The consumption of 95 % pure limestone varies between ca. 1100 and 1200 kg/1000 kg sodium carbonate, and is therefore approximately 10 – 20 % higher than the theoretical value.

In the system $CaCO_3 \rightleftharpoons CaO + CO_2$, the equilibrium pressure of CO_2, p_{CO^2} varies logarithmically with absolute temperature T

$$\log p_{CO_2}\ (\text{bar}) = -\frac{8580}{T\,(\text{K})} + 7.26$$

Thus the CO_2 vapor pressure at ca. 900 °C is 0.1 MPa. However, at this temperature, decomposition is too slow. If the rate of decomposition is increased by increasing the temperature dead-burnt limestone may be produced, which does not react with water. The best calcination temperature, therefore, lies between 1050 and 1100 °C.

In soda ash plants, calcination is carried out in well-insulated shaft furnaces heated with coke [11, pp. 76–83]. Furnace gas CO_2 contents of 40–42 vol % can be obtained. If liquid or gaseous fuels are used, the CO_2 content of the gas is lower.

The hot, dust-laden gas is cooled and washed by direct contact with water. It then passes to the CO_2 compressors from which it is delivered to the carbonation stage.

Quicklime from the kiln is reacted with used cooling water (50–65 °C) in horizontal rotating drums to produce a suspension of $Ca(OH)_2$ in water (milk of lime) that is as concentrated as possible. In favorable circumstances, the CaO content of the milk of lime can reach 5.5 mol/L.

Before milk of lime is used in the distillative recovery of ammonia, coarse sand and unburnt limestone are removed by sieves, mixed with new limestone, and recycled to the kiln.

Stage 3: Ammonia Absorption. Gas from the distillation stage (stage 7) contains NH_3 and CO_2, and is saturated with water vapor. In the absorption stage, this gas is absorbed by purified brine. Here, the total amount of ammonia required in the process and ca. 20 % of the required carbon dioxide are added. The ammoniacal brine obtained contains ca. 85–90 kg/m^3 NH_3 and 40–50 kg/m^3 CO_2. The NaCl content is reduced from ca. 300–260 g/L due to the increase in the specific volume of the liquor caused by the addition of ammonia and by dilution with water.

The reactions that occur during absorption are strongly exothermic and can be represented by the following equations:

$$NH_3 + H_2O \longrightarrow NH_4OH\ \Delta H = -34\,900\,\text{kJ}$$

$$2\,NH_4OH + CO_2 \longrightarrow (NH_4)_2CO_3 + H_2O\ \Delta H = -90\,850\,\text{kJ}$$

The absorption towers are equipped with effective internal or external coolers to remove the heat of reaction and the sensible heat of the distillation gas (total: ca. 1.84 GJ/t sodium carbonate). A typical absorption plant consists of a tower containing eight bubble trays and an external intermediate cooler (Fig. 6).

Figure 6. Absorption equipment with gas scrubbers
a) Brine distributor; b) Calcination gas scrubber; c) Filter gas scrubber; d) Absorption gas scrubber; e) Making column scrubber; f) Absorption; g) Absorption cooler; h) Reservoir

Stage 4: Precipitation of Bicarbonate (Making). The precipitation of sodium bicarbonate

$$NaCl + NH_4HCO_3 \longrightarrow NaHCO_3 + NH_4Cl$$

is an exothermic process in which ammoniacal brine from the absorption stage is reacted with carbon dioxide from the lime kiln (stage 2) or from the calcination stage (stage 6). In most ammonia–soda plants, cast iron columns of the type shown in Figure 7 are used for this reaction. In this double-tray column, which is equipped with tubular coolers in the lower part, ammoniacal brine is carbonated in countercurrent flow. The cooling water, also in countercurrent flow, must remove ca. 1.42 GJ/t of heat.

Figure 7. Making column
a) Double tray; b) Cooling tube bundle

Making columns become coated with the precipitated bicarbonate, which covers the inner parts including the cooling tubes, and must therefore be cleaned after 3 – 4 d of operation. This is carried out by washing with fresh ammoniacal brine while a stream of carbon dioxide gas is bubbled through (precarbonation). The washing liquor is then fed in parallel to the remaining columns, where it is carbonated in two stages. In the upper part of the columns (above the tube bundles), so- called weak gas (lime kiln gas) is used for carbonation, whereas in the lower part, more highly concentrated strong gas – a mixture of kiln gas and calcination gas – is used.

A distribution system for the liquid and gas streams enables each column to be used for either cleaning or making. In general, one out of four or five columns is a cleaning column.

A few soda ash plants still use the Honigmann process, in which carbonation is carried out in three to five vessels. CO_2- containing gas is bubbled through a central dip tube into the ammoniacal brine. Gas with the highest CO_2 content (calcination gas) is supplied to the vessel with the most strongly carbonated ammoniacal brine, and weak gas is fed to the vessel that contains fresh solution.

The temperature profile in both column and vessel processes exhibits a maximum of 50 – 60 °C. The suspension of bicarbonate in mother liquor leaves the carbonation stage at 30 °C.

Stage 5: Filtration of Bicarbonate. Bicarbonate is generally separated from the mother liquor in continuous rotary vacuum filters or band filters, and sometimes in centrifuges. Mother liquor adhering to the bicarbonate crystals is washed off with condensate produced during the production process or with softened water. The quantity of washing water required depends on the particle size of the precipitated product and varies between 0.3 and 1 m^3/t of bicarbonate.

Crude bicarbonate has the following approximate composition: $NaHCO_3$, 75.6 %; Na_2CO_3, 6.9 %; NH_4HCO_3, 3.4 %; $NaCl + NH_4Cl$, 0.4 %; H_2O, 13.7 %.

Centrifuged products contain only 7 – 9 % water. Calcination of 1 t of crude bicarbonate yields ca. 520 – 560 kg of soda ash.

Stage 6: Calcination of Bicarbonate. Thermal decomposition of crude bicarbonate to carbonate liberates carbon dioxide, ammonia, and water vapor. The product is technical-grade soda ash, which contains sodium chloride. The main reaction is

$$2\,NaHCO_3 \longrightarrow CO_2 + H_2O + Na_2CO_3$$

and side reactions are

$$NH_4HCO_3 \longrightarrow NH_3 + CO_2 + H_2O$$

$$NaHCO_3 + NH_4Cl \longrightarrow NH_3 + CO_2 + H_2O + NaCl$$

The heat requirement for the calcination of crude bicarbonate is 0.92 GJ/t soda, not including that required for drying the moist, filtered product. The total heat requirement for calcination in rotary calciners is 3.7 GJ/t soda. This heat is supplied at ca. 180 °C; the decomposition temperature of $NaHCO_3$ is 87.7 °C at a total $CO_2 - H_2O$ pressure of 0.1 MPa.

Calcination is generally carried out in rotary calciners. These are heated either externally with oil, gas, or coal, or internally with steam, which passes through heating tubes in the calciner countercurrent to the flow of solid material. Condensing steam gives much better heat

transfer than combustion gas, so that the output from steam-heated rotary calciners is considerably higher than that of calciners heated by combustion processes. The advantages of steam-heated calciners compared with those heated by combustion include the absence of thermal damage to the calciner, smaller space requirements and hence lower equipment costs, and ca. 15 % less fuel consumption.

Gases extracted from the calciners contain CO_2, NH_3, H_2O, and some leakage air, together with large amounts of dust (sodium carbonate and bicarbonate), which is removed in cyclones or electrostatic filters. Before this gas is used in the carbonation stage, it is cooled and washed with brine and water until it is free of ammonia. The condensate produced at this point is fed to the ammonia recovery stage.

If the soda ash is required in the form of solution or hydrated crystals, wet calcination can be used. This is carried out in a tower with steam in countercurrent flow. In this thermal decomposition, a sodium carbonate – sodium bicarbonate equilibrium is established, which limits the yield to 85 – 88 %.

Stage 7: Recovery of Ammonia. Ammonia, present in the filtrate as ammonium carbonate, hydrogencarbonate, sulfate, and chloride, is recovered by distillation followed by absorption. Both $(NH_4)_2CO_3$ and NH_4HCO_3 are completely decomposed at 85 – 90 °C, liberating all of the carbon dioxide and a small part of the ammonia from solution. Liberation of ammonia from NH_4Cl and $(NH_4)_2SO_4$ requires reaction with milk of lime:

$$2\,NH_4Cl + Ca(OH)_2 \longrightarrow 2\,NH_3 + 2\,H_2O + CaCl_2$$

$$(NH_4)_2SO_4 + Ca(OH)_2 \longrightarrow 2\,NH_3 + 2\,H_2O + CaSO_4$$

This reaction must be preceded by thermal decomposition of $(NH_4)_2CO_3$ and NH_4HCO_3 to avoid precipitation of calcium carbonate and consequent consumption of additional milk of lime. Free ammonia is displaced from solution with low-pressure steam.

A distillation plant is shown schematically in Figure 8. Distillation gas, which contains NH_3 and CO_2, is cooled to ca. 55 – 60 °C in the still condenser and still preheater. At this temperature, no danger exists of blocking the pipework with crystallized salts formed by ammonia and carbon dioxide. The stripping still removes CO_2 and NH_3 by thermal decomposition of $(NH_4)_2CO_3$ and NH_4HCO_3, and in the prelimer, NH_4Cl and $(NH_4)_2SO_4$ are reacted with milk of lime. In the distillation column the ammonia content of the liquor is lowered to ca. 0.5 kg/t sodium carbonate by steam treatment. The CO_2 – NH_3-containing condensate from the gas cooler and heat exchanger is recycled to the stripping still or distilled in a special condensate tower.

Figure 8. Flow diagram of stripping equipment

1.4.2. Modified Ammonia – Soda Process

Many variants of the ammonia – soda process exist [20]. Here, only the dual process, developed and operated in Japan, is described. This process combines soda ash production with ammonium chloride production. The importance of the process in Japan is due to the high cost of imported rock salt and use of the ammonium chloride as a fertilizer.

In the dual process [13] (see Fig. 9), ammonia is absorbed by the bicarbonate mother liquor, and solid sodium chloride is added. On cooling, ammonium chloride separates, is recovered in centrifuges, and is then dried in rotary dryers with air at 150 °C. The mother liquor is recycled to the carbonation towers where sodium bicarbonate is precipitated.

Figure 9. Flow diagram of the dual process
Solution A: 4.1 mol/L NH_4Cl + 1.05 mol/L NaCl; ϱ = 1.108 g/cm^3; t = 20 °C
Solution B: 3.45 mol/L NH_4Cl + 1.1 mol/L NaCl; ϱ = 1.110 g/cm^3; t = 5 °C
Solution C: 1.86 mol/L NH_4Cl + 3.73 mol/L NaCl; ϱ = 1.187 g/cm^3; t = 10 °C

Important differences exist between equipment used for the conventional Solvay process and that used for the ammonium chloride – soda process. In the dual process, ammonia is not recovered; hence no distillation equipment is required. Also, lime kilns are not required if other sources of CO_2 are available. Because of the extremely corrosive properties of NH_4Cl-containing solutions, they are produced in equipment made of special cast iron or plastics. As the mother liquor is recycled, special attention must be paid to the water balance of the system. The amount of water introduced into the system (e.g., for washing sodium bicarbonate and ammonium chloride) must be controlled continuously to maintain the correct quantity and composition. The quantity of sodium carbonate produced in 1970 by the dual process amounted to ca. 4.7 % of world production [14].

1.4.3. Production from Trona and Other Sodium Carbonate-Containing Minerals

The production of soda ash from trona in the United States has become significant since World War II. The raw material is either a naturally occurring brine containing sodium carbonate (e.g., from Searles Lake in California) or a trona deposit (e.g., from the Green River region of Wyoming).

Sodium carbonate brines are pumped from the lake and treated with CO_2 gas to precipitate sodium bicarbonate, which is filtered, washed, and calcined to form sodium carbonate.

In another process, the liquor is evaporated in solar ponds until trona ($Na_2CO_3 \cdot NaHCO_3 \cdot 2\,H_2O$) crystals separate. The trona contains ca. 45 % Na_2CO_3, 35 % $NaHCO_3$, 2 % NaCl, 1.5 % Na_2SO_4, 0.1 % SiO_2, 0.2 % insolubles, and 16 % H_2O. Calcination yields a product containing 95 – 96 % sodium carbonate.

In 1937, a large deposit of trona was discovered in the Green River region of Wyoming, but its significance was not recognized at first. Drilling work, which continued from 1944 to 1947, gave the first indication of the size of the deposit, which was subsequently extracted by the companies FMC, Stauffer Chemical, Allied Chemical, Texas Gulf (after 1976), and Tenneco Oil (after 1982) [15]. At first, mined trona (ca. 40 000 t/a) was simply calcined to produce crude sodium carbonate, but by 1952 an FMC plant was producing 300 000 t/a of purified sodium carbonate. Drilling work during the last 30 years has revealed reserves of $> 50\,000 \times 10^6$ t, mainly at depths of 250 – 450 m.

Natural trona from these deposits is a colorless or white mineral with a density of 2.13 g/cm^3 and a Mohs hardness of 2.5 – 4. The deposits generally contain > 90 % trona, with halite (NaCl), shortite ($Na_2CO_3 \cdot 2\,CaCO_3$), pyrite (FeS_2), shale, and other rock minerals. The United States now obtains its sodium carbonate entirely from trona; production capacity in 1991 was 9.88×10^6 t [15].

Processing is carried out mainly by the monohydrate process (see Fig. 10). Trona is crushed to < 6 mm and calcined at 300 °C in a rotary furnace to remove water of crystallization and convert the bicarbonate to carbonate. The calcined material is agitated with water to dissolve the crude soda ash. Insoluble components such as silica, sodium silicate, and gangue are removed by classifiers. The insoluble residues are then extracted with water. The concentrated liquor containing dissolved sodium carbonate is transferred to a thickener where the remaining finely divided insoluble residues are precipitated with flocculating agents. The clarified concentrated liquor is further purified by filter presses, and residual organic impurities are removed with activated carbon. The almost saturated solution is then evaporated in multiple-effect evaporators to give a 30 % slurry of $Na_2CO_3 \cdot H_2O$. This is followed by concentration to a 60 % solids content in hydrocyclones and centrifugation. The centrifuged monohydrate crystals, which still contain 2 – 8 % water, are calcined in rotary furnaces, while the filtrate is recycled to the process. The calcined product is ground to the required particle size and then sent to the storage silo.

In the sodium sesquicarbonate process, trona is first subjected to a multistage solution process to remove impurities. After vacuum crystallization, the sesquicarbonate crystals produced are separated from the mother liquor by centrifugation and calcined in rotary furnaces.

The largest trona deposit outside the United States is located at Magadi Lake in Kenya. This has an area of 65 km^2 and a thickness of 30 m, and is extracted by open-cast mining. Since 1990, the production capacity of the Magadi-Soda Co. (a subsidiary of Penrice Soda Products of Australia) has been 275 000 t/a [15–18].

1.4.4. Other Processes

Leblanc Process. The Leblanc process, which is now of only historical interest, is based on the following reactions:

$$2\,NaCl + H_2SO_4 \longrightarrow Na_2SO_4 + 2\,HCl$$

$$Na_2SO_4 + 2\,C \longrightarrow Na_2S + 2\,CO_2$$

$$Na_2S + CaCO_3 \longrightarrow Na_2CO_3 + CaS$$

The first plant using this process began operating in 1790 with a production of 300 t/d. By 1870, England had 40 factories and Germany 20. From 1885, Leblanc soda ash production declined because of competition from the more economical Solvay process, which also resulted in a higher-quality product. In England, the United Alkali Co. ceased production by the Leblanc process in 1916, and in Germany, Chemische Fabrik Rhenania in Stolberg, the last company using the process, operated until 1923.

A major disadvantage of the Leblanc process compared to the Solvay process is that it involves mainly solid-phase reactions and consumes large amounts of energy (at red heat or just below). The waste products calcium sulfide and hydrochloric acid are another disadvantage. Calcium sulfide caused both atmospheric and water pollution.

Production from Nepheline. In the former Soviet Union, pottery clay is produced from nepheline; the process also yields some sodium carbonate [19]. Finely ground nepheline is intimately mixed with very pure limestone, and the mixture is sintered. The following reaction takes place:

$$(Na, K)_2O \cdot Al_2O_3 \cdot 2\,SiO_2 + 4\,CaCO_3 \longrightarrow (Na, K)_2O \cdot Al_2O_3 + 2\,(2\,CaO \cdot SiO_2) + CO_2$$

The clinker produced is ground with water to dissolve the sodium and potassium aluminates. The aluminate solution is then treated with CO_2-containing gas (e.g., combustion gas), to precipitate aluminum oxide hydrate and give a solution of alkali-metal carbonates:

$$(Na, K)_2O \cdot Al_2O_3 + CO_2 + 3\,H_2O \longrightarrow 2\,Al(OH)_3 + (Na, K)_2CO_3$$

The solution is evaporated and separated into fractions containing various proportions of sodium and potassium carbonate, which differ in solubility. The bicarbonates present in these solutions are converted to carbonates by treatment with alkali-metal hydroxide solution before evaporation.

In the process for converting nepheline to aluminum oxide, 4 t of nepheline gives ca. 1 t of sodium carbonate.

Other Proposed Modifications of the Ammonia – Soda Process. Attempts to produce sodium carbonate by other methods have been unsuccessful [20], [21]. A few proposals are mentioned here, although these have not been adopted industrially.

1) According to [22], recovery of ammonia by distillation can be avoided by using an intermediate salt; hydrochloric acid is produced in addition to sodium carbonate. The process consists of two stages. In the first, sodium bicarbonate is precipitated from an ammoniacal solution of sodium sulfate:
$2\,NH_3 + 2\,CO_2 + 2\,H_2O + Na_2SO_4$
$\longrightarrow (NH_4)_2SO_4 + 2\,NaHCO_3$
In the second stage, sodium sulfate is regenerated from the mother liquor produced in the above reaction. Here, either pure ammonium sulfate is precipitated in the first step,
$Na_2SO_4\,(s) + (NH_4)_2SO_4\,(aq)$
$\longrightarrow Na_2SO_4\,(aq) + (NH_4)_2SO_4\,(s)$
or a double salt is produced:
$2\,Na_2SO_4\,(s) + (NH_4)_2SO_4\,(aq) + 4\,H_2O$
$\longrightarrow Na_2SO_4\,(aq) + Na_2SO_4 \cdot (NH_4)_2SO_4 \cdot 4\,H_2O\,(s)$
The solid ammonium sulfate obtained is heated with sodium sulfate:
$(NH_4)_2SO_4 + Na_2SO_4$
$\longrightarrow 2\,NaHSO_4 + 2\,NH_3$
Ammonia is thereby recovered and recycled to the process.
Then, $NaHSO_4$ is fused with NaCl, to produce hydrogen chloride:
$NaHSO_4 + NaCl \longrightarrow Na_2SO_4 + HCl$
2) The following variation of the Solvay process is proposed in [23]: Ammonia from the bicarbonate mother liquor is recovered by reaction with magnesium hydroxide, not calcium oxide. Magnesium chloride and sodium chloride are present in the distillation liquor after removal of ammonia. Magnesium chloride is recovered as the monohydrate by evaporation and then decomposed:

$$MgCl_2 \cdot H_2O \xrightarrow{200\,^\circ C} MgOHCl + HCl$$

$$MgOHCl \xrightarrow{500\,^\circ C} MgO + HCl$$

The hydrogen chloride liberated is sold as such or after oxidation to chlorine, and magnesium oxide is recycled to the process. Apart from the fact that the hydrogen chloride produced is difficult to market, doubts exist that the decomposition of $MgCl_2$ is feasible in practice because of corrosion problems.
3) The following proposal was made by Blumberg et al. [24], [25]. In the equation
$NaCl + H_2O + CO_2 \rightleftharpoons NaHCO_3 + HCl$

the reaction proceeds to the right if hydrogen chloride is removed. This is achieved by reaction with a $C_8 - C_{12}$ tertiary amine dissolved in *n*-pentanol. The amine is regenerated by reaction with magnesium hydroxide. The 26 % solution of $MgCl_2$ produced is thermally decomposed to hydrochloric acid and magnesium oxide, which is recycled to the regeneration stage.

The starting material is brine containing 24 – 26 % NaCl and CO_2 dissolved at a partial pressure of ca. 0.3 MPa. Sodium bicarbonate is precipitated as a solid salt and recovered from the bottom of the vessel. The liquid separates into two phases: a solution of NaCl, which is recycled, and organic solvent saturated with hydrogen chloride. The equations are as follows:

$$NaCl + CO_2 + H_2O + NR_3 \rightleftharpoons NaHCO_3 + NR_3 \cdot HCl$$

$$NR_3 \cdot HCl + 1/2\, Mg(OH)_2 \rightleftharpoons 1/2\, MgCl_2 + NR_3 + H_2O$$

$$1/2\, MgCl_2 + H_2O \rightleftharpoons 1/2\, Mg(OH)_2 + HCl$$

The process is problematic because it results in pollution of the environment with amines and organic solvents. Another problem is the hydrogen chloride byproduct.

4) The combined production of sodium carbonate, chlorine, and a mixture of ammonium and sodium nitrates has been proposed in [26]. Sodium chloride is oxidized by excess nitric acid, to produce sodium nitrate and chlorine:

$$6\, NaCl + 6\, HNO_3 + 3/2\, O_2 \longrightarrow 6\, NaNO_3 + 3\, Cl_2 + 3\, H_2O$$

The sodium nitrate solution is neutralized with ammonia and then reacted with carbon dioxide to form sodium bicarbonate.

After the bicarbonate is filtered off, a mixture of ammonium and sodium nitrates that can be used as a fertilizer is recovered from the filtrate.

1.4.5. Wastewater Problems in Sodium Carbonate Production [27]

In the recovery of ammonia by distillation with milk of lime, an end liquor (ca. 7 – 10 m^3/t sodium carbonate) is produced at its boiling point. This liquor has the following approximate composition: 120 – 180 g/L $CaCl_2$, 1.0 – 1.7 g/L $Ca(OH)_2$, 50 – 75 g/L NaCl, 1.0 – 1.5 g/L $CaSO_4$, and 20 – 30 g/L suspended solids. These solids originate mainly from impurities in the limestone and coke, and include uncalcined or dead-burnt limestone. Also, some solid material results from the reaction of milk of lime with residual carbon dioxide not removed in the stripping still.

The solid material consists of ca. 67 % $CaCO_3$, 10 % $Mg(OH)_2 + Ca(OH)_2$, 10 % $CaSO_4 \cdot 2\, H_2O$, 10 % SiO_2, and 3 % $Fe_2O_3 + Al_2O_3$. It is very finely divided and therefore difficult to remove. The liquor is often clarified in large settling basins or ponds. However, mud with a high chloride content is produced, which presents disposal problems. Therefore, the end liquor is frequently diluted with used cooling water and discharged directly into the receiving water body. This method of disposal is generally recognized as safe because calcium carbonate, which is the main solid component in the wastewater, reacts with carbon dioxide in the water to form calcium bicarbonate solution.

The amount of $CaCl_2$ in the end liquor is given by the overall equation for the Solvay process:

$$2\, NaCl + CaCO_3 \longrightarrow Na_2CO_3 + CaCl_2$$

This shows that the reaction produces 1 mol $CaCl_2$ in the end liquor for each mole of Na_2CO_3 produced. The end liquor also contains some NaCl resulting from incomplete reaction. Removal of chloride from the end liquor should be considered only if at least some of it can be used to produce calcium chloride. However, this is carried out in only a few sodium carbonate plants, because the demand for this chemical is relatively low.

1.5. Quality Specifications

The product obtained by the ammonia – soda (Solvay) process is, after calcination, an anhydrous, technical-grade sodium carbonate. The two main commercial forms are light soda ash and dense soda ash, which differ in particle size and bulk density. Light soda ash has a bulk density of 0.5 – 0.6 kg/L; dense soda ash 1.05 – 1.15 kg/L.

The quality of the product is normally assessed by the following tests:

1) Loss on heating at 250 °C
   Method: Drying of sample at 250 °C for 2 h in a crucible furnace
2) Water-insoluble material
   Method: Determination of residues insoluble in water at 50 °C
3) Total alkalinity expressed as Na_2CO_3
   Method: Titration with 1 M hydrochlorid acid, with methyl orange as indicator
4) Sodium bicarbonate ($NaHCO_3$)
   Method: Winkler titration – conversion of $NaHCO_3$ to Na_2CO_3 by addition of a known amount of NaOH; precipitation of total CO_2 as $BaCO_3$; back titration of excess NaOH with HCl (indicator: phenolphthalein)
5) Sodium carbonate (Na_2CO_3)
   Calculation: Total alkalinity (method 3) minus alkalinity due to $NaHCO_3$ (method 4)
6) Sodium chloride (NaCl)
   Methods:
   a) Mohr's titration against 0.1 M $AgNO_3$, with K_2CrO_4 as indicator
   b) Argentometrically with potentiometric determination of the end point
7) Sodium sulfate (Na_2SO_4)
   Method: Gravimetrically by precipitation of the sulfate as $BaSO_4$
8) Iron oxide (Fe_2O_3)
   Method: Colorimetric (photometric) determination of the concentration of Fe(II)–dipyridyl complex
9) Water (H_2O)
   Calculation: Weight loss at 250 °C (method 1)minus wight loss due to $CO_2 + H_2O$ determined from decomposition of $NaHCO_3$ ($NaHCO_3$ by method 4).

A typical analysis is given below:

Na_2CO_3	99.6 %	Fe_2O_3	0.002 %
NaCl	0.15 %	CaO	0.01 %
Na_2SO_4	0.02 %	MgO	0.02 %

In addition to its chemical analysis, the product is also characterized by particle size and bulk density.

For soda ash produced from trona, the following are typical analysis figures:

Na_2CO_3	99.6 %	Fe_2O_3	0.001 %
NaCl	0.035 %	CaO	0.01 %
Na_2SO_4	0.1 %	MgO	0.003 %

The difference in particle-size distribution between light and dense soda ash is shown by the following value:

	Light ash (%)	Dense ash (%)
> 2 mm	0.1	0.2
2 – 1 mm	0.5	5
1 – 0.5 mm	1	26
0.5 – 0.25 mm	10	50
0.25 – 0.125 mm	30	14
0.125 – 0.063 mm	38	4
< 0.063 mm	20.4	0.8

Soda ash of the quality described above is suitable for most applications and is usually adequate for the food industry.

Other, special grades include dense granulated soda and briquetted soda. So- called washing soda crystals, the decahydrate $Na_2CO_3 \cdot 10\,H_2O$, is now of minor importance. This is produced from calcined sodium carbonate by dissolving it in boiling water until the density is 30 – 40° Bé. Hard crystals are obtained only if the solution contains some sulfate, and a small percentage of this substance is therefore added to the solution. The solution is clarified by allowing solid impurities to sediment. The solution is then cooled to 38 °C in crystallizing troughs to obtain soda crystals. A typical analysis of the commercial product is 36.6 % Na_2CO_3, 0.03 % NaCl, 0.15 % Na_2SO_4, 63.22 % H_2O.

1.6. Producers

Western Europe producers of soda ash are listed below:

Country	Company	Location
Germany	Solvay Deutschland GmbH	Rheinberg, Heilbronn, Bernburg
	Chemische Fabrik Kalk GmbH *	Köln-Kalk
	Matthes & Weber GmbH	Duisburg
	Sodawerk Stassfurt GmbH	Stassfurt
Belgium	Solvay S.A.	Couillet
France	Solvay S.A. Rhône-Poulenc	Dombasle La Madeleine
Italy	Solvay S.A.	Rosignano
Netherlands	AKZO	Delfzijl
Portugal	Soda Povoa SARL (Solvay subsidiary)	Povoa de Santa Iria
Spain	Solvay S.A.	Torrelavega
United Kingdom	Penrice Soda Products Ltd.	Winnington

* Closure planned for end of 1993.

In Eastern Europe plants in the following countries are producing soda ash by the Solvay process: Bulgaria, Poland, Romania, the former Yugoslavia, and the CIS.

The United States has the following production plants:

FMC Corporation	Green River, Wyoming
General Chemical Corp.	Green River, Wyoming
North American Chemical	Argus, California
Rhône-Poulenc	Green River, Wyoming
Solvay Minerals (formerly Tenneco) in partnership with Asahi Glass	Green River, Wyoming
Texasgulf Chemical Co.	Green River, Wyoming

The most important producers outside Europe and the United States are China, India, and Japan.

1.7. Storage and Transport

Calcined soda ash is hygroscopic, gradually taking up moisture and carbon dioxide during transportation and storage. This converts the surface of sodium carbonate to the bicarbonate and leads to a weight increase of up to 17 %. Soda ash is therefore best stored in closed, dry areas.

Soda ash is supplied either bulk in silo wagons that can be discharged pneumatically or in paper sacks.

Soda crystals (washing soda) can effloresce or dissolve in the water of crystallization, depending on the temperature and relative humidity. They melt at 32 – 33 °C. At lower temperature, they are stable, provided the relative humidity is within the limits listed below:

T, °C	0	10	15	25
R.H., %	59 – 98	64 – 96	68 – 94	76 – 87

At lower humidity, soda crystals effloresce, and at higher humidity the surface becomes wet.

1.8. Uses

Soda ash is an important raw material for the chemical industry. Its sodium content results in fluxing properties that make it important in the glass and silicate industries. It is used to neutralize inorganic and organic acids or acidic salts, and to maintain a constant pH in processes where acids are liberated. It is also utilized in the production of sodium salts (e.g., phosphates, nitrates, chromates, citrates, tartrates, salts of fatty acids).

Soda ash can be used in aqueous solution to remove sulfur dioxide from process gas or off-gases, forming sodium sulfite and sodium bicarbonate:

$$Na_2CO_3 + SO_2 \longrightarrow Na_2SO_3 + CO_2$$

$$CO_2 + Na_2CO_3 + H_2O \longrightarrow 2\,NaHCO_3$$

$$2\,Na_2CO_3 + SO_2 + H_2O \longrightarrow Na_2SO_3 + 2\,NaHCO_3$$

These reactions are also important in the production of paper pulp by the sulfite process.

Other uses of sodium carbonate are as follows:

Chemical industry:

production of bleaching agents, borax, chromates and dichromates, fertilizers, dyes, fillers, tanning agents, industrial cleaning agents, catalysts, cryolite, adhesives, metal carbonates, sodium nitrate, perborates, phosphates, silicates, ultramarine pigments, soluble silicates, etc.

Detergent and soap industry: manufacture of detergents and saponification of fats.

Petrochemicals: neutralization.

Pulp and paper Industry: cooking wood; neutralization, cleaning, bleaching, and treatment of recycled paper.

Artificial silk industry: deacidification of artificial silk.

Textile industry: dyeing, bleaching, and finishing of wool and cotton.

Coke ovens, gasworks, and hydrogenation plants: gas purification (desulfurization).

Iron and steel industry: removal of sulfur and phosphorus from pig iron, cast iron, and steel; ore beneficiation, flotation agents, and fluxing agents.

*Heavy-metal industry:*digestion and beneficiation of ores (e.g., of antimony, lead, chrome, cobalt, nickel, bismuth, and tin).

Glass industry: raw material for the glass melt and for reacting with sand.

Aluminum industry: reaction with bauxite.

Ceramics industry: production of refractory materials and glazes.

Enamel industry: as a flux.
*Food industry:*hydrolysis of proteins, production of margarine and starch, and softening of sugar beet juice.
Various branches of industry: water treatment, metal degreasing.
Environmental protection:

1) Purification of flue gases by injecting sodium carbonate or sodium hydrogencarbonate (dry process).
2) Regeneration of acidic lakes by the introduction of briquettes of sodium carbonate, so that organic sediments exhibit an alkaline reaction over a long period.

1.9. Toxicology

The lowest known lethal dose of sodium carbonate is 4000 mg/kg (rat, oral). Toxic effects do not occur under normal working conditions. For humans, oral ingestion of > 15 g is potentially lethal. In case of ingestion, vomiting should not be induced, but copious amounts of water and dilute lemon juice or vinegar (two tablespoons per glass of water) should be drunk. The stomach can be carefully irrigated for 15 min at most, with the usual precautions, but use of this treatment for longer periods is strongly contraindicated (danger of perforation). Medical help should be sought.

Because of its alkaline reaction, sodium carbonate has a irritating effect on the skin and mucous membranes. If skin is attacked, the affected part should be thoroughly washed with copious quantities of water, and a nonirritant dressing applied if necessary. If eyes are splashed with sodium carbonate, the eyelids should be held open while the eye is treated for several minutes with running water or saline solution. Medical help should be sought from a specialist.

1.10. Economic Aspects

The production of soda ash increased continuously after World War II until 1975.

World production figures (in 10^6 t) are given below:

1900	1.5	1965	16.6
1913	2.85	1970	20.0
1932	5.0	1975	24.9
1940	7.0	1980	28.9
1951	11.0	1985	29.4
1960	12.7	1990	32.3

Regional figures are listed in Table 4. The proportion of soda ash produced from trona has increased continuously in the United States from 15 % in 1960, to 70 % in 1975, and 100 % since 1986. In 1991, 28 % of worldwide soda ash capacity was based on trona or other minerals containing sodium carbonate [15].

Figure 11. Solubilities in the system $H_2O - NaHCO_3 - Na_2CO_3$ at 24.9 °C, 30 °C, and 50 °C [29]

2. Sodium Hydrogencarbonate

2.1. Properties

Some physical properties of sodium hydrogencarbonate are given below:

M_r	84.007
Density	2.22 g/cm^3
Specific heat capacity (25 °C)	87.7 kJ mol^{-1} K^{-1}
Enthalpy of solution	− 18 kJ/mol
Enthalpy of formation	950 kJ/mol
Refractive indices	1.380, 1.500, 1.586
Dielectric constant (25 °C)	4.39

Solubility properties are listed in Table 5. Solubility is lower in the presence of sodium carbonate.

In the system $H_2O - NaHCO_3 - Na_2CO_3$, the double salt trona $NaHCO_3 \cdot Na_2CO_3 \cdot 2\,H_2O$ occurs at > 21.3 °C. The isotherms at 24.9 °C, 30 °C, and 50 °C are shown in Figure 11, which

Table 4. Soda ash production (10^3 t) by region [15]

Region	1975	1980	1985	1990
Western Europe	5879	6747	5966	5790
North America	6819	7857	8149	9481
Latin America	588	744	774	790
Africa	101	233	270	287
Asia	1955	2332	2648	3580
Australia	150	250	300	300
Centrally planned economies	9498	10 742	11 390	12 101

indicates the ranges of existence of the solid phases at these temperatures [29], [30].

On heating, sodium hydrogencarbonate decomposes into sodium carbonate, carbon dioxide, and water:

$$2\,NaHCO_3 \longrightarrow Na_2CO_3 + CO_2 + H_2O$$

Dissociation pressures of carbon dioxide at equilibrium are as follows:

T, °C	30	50	70	90	100	110
p_{CO^2}, kPa	0.825	3.99	16.013	55.102	97.236	166.596

At room temperature, sodium hydrogencarbonate is fairly stable because of its low rate of decomposition. The aqueous solution has an only slightly alkaline reaction due to the small extent of hydrolysis.

2.2. Production

Sodium hydrogencarbonate is an intermediate in the ammonia – soda process. However, because of the content of ammonium salts, a product that satisfies the quality requirements of consumers (mainly in the food industry) cannot be obtained by drying crude bicarbonate. Moreover, a sufficiently pure product cannot be obtained by recrystallization. Therefore, it is necessary to start with an aqueous solution of sodium carbonate which is obtained either by dissolving calcined soda ash or by decomposing crude bicarbonate with steam. This is then filtered and carbonated with pure concentrated carbon dioxide, with cooling to remove the heat of reaction:

$$Na_2CO_3 + CO_2 + H_2O \rightarrow 2\,NaHCO_3 \quad \Delta H = -43.67\,kJ$$

As carbonation proceeds, sodium hydrogencarbonate precipitates. It is recovered by centrifuging and then dried with hot air (e.g., in tray dryers).

Table 5. Solubility of sodium hydrogencarbonate in water

T, °C	Solubility	
	g/100 g solution	g/100 g H_2O
– 2.35	6.26	6.68
0	6.4	6.9
10	7.6	8.2
20	8.7	9.6
30	10.0	11.1
40	11.3	12.7
50	12.7	14.5
60	14.2	16.5
80	16.5	19.7
100	19.1	23.6

2.3. Uses and Quality Specifications

Sodium hydrogencarbonate is used in the manufacture of baking powder, as a medicament for neutralizing stomach acid, as a component of effervescent powders, in animal feed, and as a dry-powder fire extinguisher.

The following analysis is typical for the food-grade product: $NaHCO_3$, 99.7 %; Na_2CO_3, 0.2 %; NaCl, 0.004 %; H_2O, 0.05 %; insolubles, 0.003 %.

Sodium hydrogencarbonate tends to form lumps in the presence of moisture or under pressure. On heating to > 60 °C, appreciable decomposition to sodium carbonate occurs. The bicarbonate readily picks up odors from its surroundings and should therefore be stored under dry, airtight conditions.

1. History [1-6]

Gisbert Westphal

The history of mankind is also a history of salt. Although it is not clear how man learnt of its effects and its savory properties, salt has been mentioned in literature for thousands of years.

In the Odyssey, HOMER wrote: “travel . . . until you meet mortals who do not know the sea and who never eat food seasoned with salt.” Elsewhere he refers to salt as “holy.” CASSIODORUS said: “Gold can be dispensed with, but not salt.” Other notable historical sources that refer to salt include PLUTARCH, PLINY, HERODOTUS, the Old and New Testaments, and ancient Chinese writings.

Before the industrial revolution in the 1800s, salt was used almost entirely as a foodstuff and as a preservative. Its importance led people of all cultures to strive to find ways of obtaining this important, life-sustaining substance. The coastal regions of the Earth were the favored areas for salt production. Possibly the oldest mine in the world was worked in ca. 1000 B. C. at Hallstatt, Austria which gave its name to the “Hallstatt Culture.” In Germany, salt was probably first won in Schwäbisch Hall in ca. 500 B. C. The well-known salt deposit in Wieliczka, Poland was first mentioned in the 1100s. Wherever natural brine was available or early methods of brine production were practiced, a large number of salt works came into being between the 1100s and 1700s.

Salt was used universally, but was not everywhere available from natural sources, so that trading rapidly became important. The extent to which salt was used as an article of commerce is shown by the appearance of the famous salt roads in China, Africa, and Europe, and by the foundation of towns such as Salzburg, Salzach, Hall, Hallein, and Heilbronn (Celtic: *hal* = salt). Also, salt was used as currency (hence the word “salary”) and as source of tax revenue. Ancient Rome had a salt tax, and salt monopolies were established in many countries and continue to exist in Austria and Switzerland. Starting in 1765, Prussia demanded an annual salt payment from its citizens, and in Germany a tax of € 60/t was levied on all salt used in food. The total revenue from this in 1990 was € 24×10^6. This tax was discontinued at the beginning of 1993, following the establishment of the European single market.

With the advent of the industrial revolution, the use of salt as a chemical raw material increased rapidly. Industrial salt production, whether by evaporation in salt works or from mined rock salt, continually increased in importance.

Another important process of recent decades is controlled solution mining.

Although salt is no longer the cause of warlike confrontations, it has certainly lost none of its fascination, whether as a life-giving condiment or as an indispensable, versatile raw material.

Many museums, e.g., the German Museum in Munich and the German Salt Museum, Lüneburg, have comprehensive exhibitions on the history of salt.

2. Properties [7]

Gerhard Kristen

Sodium chloride, NaCl, M_r 58.443, is a colorless salt with good solubility in water. Chemically pure NaCl crystallizes from aqueous solutions in well-formed cubes, which under the influence of surface tension often grow together into funnel-shaped, hollow, square-based pyramids. In the presence of impurities, octahedra or dodecahedra are sometimes formed. Crystallization from hydrochloric acid solution gives long, fibrous, needle-shaped crystals.

During crystallization, small amounts of water can be trapped in holes in the crystals. When this vaporizes on heating, it causes the crystals to explode with audible decrepitation. In salt from natural deposits, inclusions of gases such as methane, carbon dioxide, and hydrogen sulfide can occur.

In the crystal, the Na and Cl ions alternate. The ions of each type form a face-centered cubic lattice, in which each ion is surrounded octahedrally by six ions of the other type at a distance of $a/2$ (lattice constant a = 0.56273 nm). The modulus of elasticity perpendicular to the surface of the cube is 41 074 MPa. Under high pressure, slow flow takes place. Sodium chloride is highly transparent to light of wavelength between 200 nm (ultraviolet) and 15 µm (infrared). Ionizing radiation causes lattice defects (color centers) which give the salt a blue color. On heating to ca. 250 °C, this color disappears.

Some important physical properties are listed below and in Tables 1-3.

Melting point	801 °C
Boiling point	1465 °C
Density at 25 °C	2.1615 g/cm^3

Mohs hardness	2 – 2.5
Brinell hardness	14 HB
Dielectric constant	5.9
Refractive index n_D^{20}	1.5443
Electrical resistivity at 20 °C	4.6×10^{16} Ω cm
Electrical resistivity at 100 °C	1.38×10^{13} Ω cm
Thermal conductivity at 17 °C	0.072 W cm^{-1} K^{-1}
Linear coefficient of expansion	40.5 µm/mK
Specific heat capacity at 25 °C	850 J kg^{-1} K^{-1}
Enthalpy of formation at 25 °C	–410.9 kJ/mol
Entropy at 25 °C	72.36 J mol^{-1} K^{-1}
Latent heat of fusion	0.52 kJ/g
Latent heat of evaporation	2.91 kJ/g
Viscosity of saturated aqueous solution	1.93 mPa · s
Density of molten NaCl at 801 °C	1.549 g/cm^3
Viscosity of molten NaCl at 850 °C	1.29 mPa · s
Surface tension of molten NaCl at 850 °C	110 mN/m
Electrical conductivity of molten NaCl at 850 °C	3.7 S/cm

Thermodynamic properties of aqueous solutions are given in [8].

In the system NaCl – H_2O (Fig. 1), only one hydrate, NaCl · 2 H_2O, exists. It crystallizes as monoclinic, thin, bevelled platelets that decompose to solid sodium chloride and saturated brine at 0.15 °C. Below this temperature it is the stable solid phase. However, it crystallizes so slowly that, on rapid cooling, the phase diagram follows the broken curve in Figure 1. The metastable eutectic point reached is ca. 1.3 K below the true cryohydric point at – 21.12 °C. Its property of depressing the freezing point of water enables sodium chloride to be used in freezing mixtures and as a de-icing salt. The saturated aqueous solution boils at 108.7 °C.

Sodium chloride has good solubility in aqueous ammonia (Table 4). At low temperatures, fine white needles of composition NaCl · 5 NH_3 separate out. Addition compounds with urea, glucose, and sucrose also exist. Solubilities in pure methanol and pure ethanol at 25 °C are 1.31 and 0.065 g NaCl/100 g solvent, respectively. Sodium chloride is also soluble in glycerine, and dissolves in high pressure steam, the solubility being 0.1 % at 17 MPa, and 0.6 % at 19.5 MPa. Chemically pure sodium chloride is not hygroscopic, but if magnesium salts are present as an impurity it becomes so. Sodium chloride solutions are corrosive to base metals, and therefore dilute solutions of NaCl are used in corrosion tests (e.g., DIN 50 907). Solutions of pure NaCl are more corrosive than those that also contain salts of Mg or Ca [10]. Iron and steel are attacked only fairly slowly by pure NaCl solutions, but much more quickly when the solutions contain oxygen. Corrosion by NaCl solutions is accelerated by the presence of local electrolytic cells [11]. Mixtures of organic acids with sodium chloride, (e.g., in perspiration) are highly corrosive [12].

Table 4. Solubility of sodium chloride in aqueous ammonia at 20 °C [9]

[NH_3], g/L	15.38	30.06	62.56	92.97

3. Formation and Occurrence of Salt Deposits [13]

Gerhard Kristen

When rocks are chemically weathered, salts are dissolved, carried into natural running waters, and collect in the oceans and inland lakes and seas. Where evaporation is predominant, the salts become concentrated until the solutions become supersaturated and crystallization occurs.

The proportion of sodium chloride in the salts of seawater is ca. 78 %. Although the oceans contain the largest quantity of dissolved salts, the majority of salt is bound in the form of solid deposits. In Germany alone, the quantity is estimated to be ca. 100 000 km^3.

The chemical-sedimentary genesis of salt deposits has been accepted ever since OCHSENIUS (1877) proposed his bar theory. Inspired by the contemporary example of the Kara-Bugas bay (Caspian Sea), he suggested that bodies of seawater became almost completely isolated from the open sea by bars. Then, due to the evaporation that took place in arid climatic regions, the seawater became concentrated. The sparingly soluble carbonates and sulfates were the first to

crystallize, followed by the more soluble chlorides.

In the case of the most important European salt deposit, the Zechstein Formation, communication with the North Sea has been proved by fossil finds, thus demonstrating the marine origin of the Zechstein salts, which extend over ca. 500 000 km^2 from England to Central Poland, and from Denmark to Thuringia/Hesse (Germany). The bar theory can satisfactorily account for even the 800 – 1000 m thickness of the Zechstein salt deposit, and is also valid, in modified form, for marine salt deposits. A depth of 100 m seawater produces a salt layer only 1.5 m thick on complete evaporation.

It is now believed that, for the European Zechstein salt deposit, the salt lakes were connected to the ocean by an extended saturation shelf lake where considerable amounts of $CaSO_4$ were deposited. The minor and major salt lakes were filled with salts during four largely identical deposition cycles, each having the sequence clay, calcium – magnesium carbonates and calcium sulfate, sodium and potassium chlorides, and ending with a recessive transition [sodium chloride, calcium sulfate (anhydrite), and clay] to the next cycle. The concentrations of the various soluble salts reached saturation successively as the seawater became gradually more concentrated, so forming the geographical sequence of salts. This explains why the composition does not correspond to that of normal seawater at any point in the salt profile, why all the types of salt are not deposited everywhere, why salts of differing solubilities are precipitated simultaneously at different saturation regions, and why the chlorides of potassium and magnesium are deposited only at the centers of the lakes.

The intermediate layers of clay sediments in each cycle are the result of influxes of fresh seawater. Eolian (airborne) transportation of clay minerals into the salt basin can also occur.

The depths of the brine in the deposition basins have been calculated from the bromine contents for each phase of deposition. The results obtained were: first cycle (Werra region) 330 m, second cycle in the Stassfurt region 860 m, and third cycle in the Leine region 95 m. In some cases the salt basin dried out during the third cycle. Sediments of younger formations covered and protected the Zechstein salts from dissolution.

In the North West German depression zone, a layer of overlying rock up to 5 km thick was formed. The pressure due to this denser rock, together with the interior heat of the Earth, caused metamorphosis of the salt, which became plastic and migrated. It accumulated in zones of deformation and ascended, forming salt domes (diapirs) which sometimes extended as far as the earth's surface. These were slowly dissolved by groundwater, leading to the formation of very flat secondary intermediate layers next to the overlying rock.

The upward movement of the salt during the formation of salt domes deformed the salt layers into folds, with predominantly steeply inclined strata. Under the thinner overlying rocks at the edge regions, the flat deposits remained undisturbed.

Marine rock salt deposits occur in most geological formations (see also ⟶ Potassium Compounds). In the following list, countries printed in italics have salt deposits that are economically exploited. Connected regions are separated by commas, and disconnected regions in a country by a semicolon. Countries and regions are separated by periods.

Cambrian. Canada: NW territories. Australia. *Siberia. Iran. Pakistan.*

Ordovician. Canada and United States: Williston Basin with parts of Manitoba and Saskatchewan (Canada) and parts of Dakota, Montana, and Wyoming (United States).

Silurian. United States and Canada: Salina Basin with Maryland, *Michigan, New York, Ohio*, Pennsylvania, w Virginia (United States), and Ontario (Canada).

Devonian. United States and Canada: Williston Basin with North Dakota, Montana (United States), and Alberta, Manitoba, Saskatchewan (Canada). CIS: *Siberia; Byelorussia,* Baltic, *Dnieper-Donets Basin.* Australia.

Carboniferous. Canada and United States: Williston Basin with New Brunswick and Nova Scotia (Canada), Virginia (United States), Paradox Basin with Colorado and Utah (United States). Brazil: Amazon Basin.

Permian. American Permian Basin: Colorado, *Kansas*, Oklahoma, *New Mexico*, and Texas; American Supai Basin: Arizona, New Mexico; American Williston Basin. Mexico: Chihuahua. Peru: E Cordillera. CIS: *Kama Basin*; *Donets Basin*, Volga Basin, Caspian Basin; Baltic. Bulgaria. Greece.

European Zechstein. England, *the Netherlands, Denmark, Germany, Poland.*

New Red Sandstone. Germany, *the Netherlands, Portugal.*

Muschelkalk. *Germany, France, Switzerland.*

Keuper. Germany, *England, France, Spain,* Algeria, Libya.

Triassic Alpine. *Germany, Austria.*

Triassic, unstructured. Mexico: Tehuantepec. Bulgaria. Greece. Morocco. Tunisia.

Jurassic. United States: *Idaho*, Utah; Gulf Coast: *Texas, Louisiana, Mississippi.* Cuba. *Chile. Yemen.* Kuwait. Morocco. Tadzhikistan. Germany.

Cretaceous. United States: Florida. Bolivian Cordillera, Brazil: Sergipe-Alagoas Basin, *Argentina, Colombia*. Angola, Congo, Gabon, Morocco, Algeria. Tadzhikistan.

Eocene. United States: Green River Basin Wyoming. Belize. Spain. Yugoslavia.

Oligocene. France, Germany. *Spain. Anatolia*, Caucasus Mountains, Iran, Iraq.

Miocene. *Czechoslovakia, Polish, Russian,* and *Romanian Carpathian foreland, Yugoslavia, Anatolia,* Cyprus, Syria, Iraq, Iran, Golf of Suez, *Algeria, Sicily, Tuscany, Spain.* Sudan. *Dominican Republic.*

Pliocene. United States: Nevada, Utah. Jordan, Israel.

4. Production

Wilhelm Wegener, Peter Ambatiello, Helmut Geyer, Bernard Epron, Christian Bonal

4.1. Mining of Rock Salt

Rock salt has been mined in Europe for 3000 years. A salt deposit near ground level in the Eastern Alps was developed by tunnelling and worked by excavation around 1000 B.C.

Salt-bearing regions are revealed by the presence of surface springs of saline water, and these were the areas where the possibility of mining was always investigated by sinking shafts. The main precondition for success is the presence of dry overlying rock, and it was this circumstance that enabled the first German salt mine to be opened in 1825 near Schwäbisch Hall. In other parts of Europe, salt was mined long before this, e.g., in Poland before 1000 A.D., and in England since the 1600s.

Total world production of solid salt by conventional mining and brine by solution mining is ca. 190×10^6 t. Annual production of salt in the Federal Republic of Germany in 1989 was ca. 13×10^6 t.

The purity of the salt mined from rock salt deposits is between 90 and 99 % NaCl, and sometimes higher. The other minerals present in the rock salt are mainly clay and anhydrite, often intimately intergrown.

Rock salt and potassium chloride have the same marine origin, often occurring together in a single deposit, and have essentially the same mechanical strength properties. Hence, the development and mining of rock salt deposits is similar to that of potash mineral deposits.

Mine Shafts. Access from the surface to the salt deposit is usually by vertical shafts 5 m in diameter. There must be at least two shafts, so that in case of damage to one of them, the underground workforce has an emergency route to the surface.

To sink the shaft, the rock is broken up by drilling and explosives. The rock debris is loaded into skips by grabs, and taken to the surface. In most cases, the upper layers of the overlying rock are water-bearing, and sometimes consist of unstable loose rock and moving sand capable of exerting pressure. Therefore, before sinking the shaft, these strata must be solidified and stabilized. This can be achieved by freezing via holes drilled around the area where the shaft is to be sunk. The freezing equipment must be kept in place for the duration of the sinking of the shaft.

Another method of preventing the movement of water in the overlying strata and immobilizing loose rocks is the injection of cement, synthetic resins, or other hardening materials via boreholes. This technique is also suitable for sealing the mine shaft against the ingress of water and for stabilizing the rock at the bottom of the shaft.

As rock salt is a water-soluble mineral, it is especially important to ensure that the lining of the shaft is watertight when it is sunk through water-bearing strata. In older shafts, the sealing system consists of ring-shaped sections of cast iron or steel bolted together. Newer shafts have a watertight lining consisting of a welded sheet-steel cylinder, an inner hollow cylinder of reinforced concrete, and an outer asphalt-filled ring.

Material is hoisted up the shaft in 20 t skips at rates of up to 1000 t/h. These travel between wooden or steel guide rails, or in a few cases between tensioned guide cables.

If the salt deposit appears as an outcrop, or is at low depth (< 100 m), the salt can be extracted by drift mining (tunnelling) or by means of an inclined shaft. In these cases, the salt can be transported to the surface with conveyor belts.

Mining Methods. As with any mining operation, the method of extracting salt depends on the thickness and spatial formation of the deposit.

A characteristic feature of salt mining is that the haulage and ventilation tunnels servicing the excavation chambers are driven through rock salt, whereas in other types of mine they are often coated in the adjacent rock. In salt mining this is generally not necessary, as the deposits are usually thicker. Furthermore, drilling and tunnelling into the adjacent rock should be avoided as far as possible to prevent ingress of water or gas from these strata into the mine.

Mining in Level Deposits. In most salt mines, a systematic extraction procedure is possible due to the uniformity of the deposit over large areas.

In salt deposits with horizontal or gently inclined seams, the standard method is room and pillar mining. In this method, the extraction process produces large chambers with rectangular cross sections of ca. 50 – 400 m^2 and lengths of up to 500 m. The parallel extraction chambers are separated from each other by rock salt pillars left behind during mining. These pillars must be of such dimensions that they can carry the weight of the overlying rock. Generally, additional support is not required, and the ground above is protected against subsidence.

The pressure exerted by the overlying rock increases with depth, so that the salt pillars must be wider. For example, in a salt mine at a depth of 200 m, the pillars are 15 m wide and the chambers 15 m; at a depth of 500 m, the pillars are 30 m wide and the chambers 20 m; and at a depth of ca. 700 m, the pillars are 50 m wide, and chambers 22 m. The salt pillars result in a ca. 40 – 70 % loss of product, depending on their dimensions.

The salt extraction process starts with the construction of a central haulage tunnel. At right angles to this, tunnels leading to the working faces are driven. The tunnels are developed upward or downward to form chambers if the deposit is so thick that it extends above or below them. The salt pillars produced by this mining technique are usually not cut through.

If the deposits have a workable thickness of < 10 m, the pillar and chamber method with long pillars is often changed to one with short, square pillars (room and pillar system). Here, the transverse tunnels usually have the same height and width as the long ones.

Fresh air is provided by an inlet ventilation road above the haulage tunnel. The used air is removed through return air galleries and by the main ventilating fan, which is usually underground, and blown through the exhaust shaft to the surface.

The mining of the salt during the construction of the tunnels and in the extraction chambers is by drilling and the use of explosives. Other possible methods, such as cutting the salt by part-face heading or full-section cutting machines, are used where there are special restrictions, e.g., where the winning process must be vibration free.

Various drilling and blasting processes are used. In the undercutting method, the working face is undercut to a distance of 4 – 5 m. The cut, 15 – 20 cm wide, is produced by a machine resembling a chain saw. An electro-hydraulic mobile drilling machine drills 35 – 38 mm diameter holes for the explosive. In another process, a wide hole up to 7 m in length and 0.45 m in diameter is drilled into the middle of the working face to provide an initial extension space for the salt at the moment of explosion, a function that is performed in the undercutting process by the undercut.

The extraction chambers are created by widening the access tunnels. If these are driven through the lower part of the deposit, this is performed by the use of explosives in long inclined boreholes directed upwards. If the tunnel runs through the upper part of the deposit, the salt is extracted from the floor, i.e., by drilling long holes downwards into the salt.

Figure 2 shows a vertical section through a South German mine where the rock salt deposit is 20 m thick and 200 m deep. The haulage and working roads are located in the lower part of the deposit, and the main ventilation road in the upper part. In the main extraction phase, the salt that has been broken up by explosives is left lying in the space created, and the final position of the roof of the chamber is created by blasting, working from the top of the heap of loose salt. After scaling the roof can then be collected without the danger of roof falls.

Figure 2. Vertical section through a South German salt mine

The most commonly used explosive is ANFO (ammonium nitrate fuel oil mixture) in the form of loose prills. It is charged pneumatically into the boreholes.

Due to the strength of the salt rock, it is possible in most mines to keep the mined space open without supports. At great depths, where the pressure is high, or where breakup of the deposit leads to danger to the miners from roof falls of salt, rock bolts are used.

Mining Steeply Inclined Deposits. Steep to vertical rock salt deposits are generally mined by the stepped face method, as used, for example, in North German mines at depths of 400 – 850 m, with working levels at vertical intervals of 100 – 250 m and intermediate sublevels at intervals of 15 – 20 m. Between the sublevels, there are working faces which are drilled and blasted, beginning with the lowest, using long boreholes. In one mine, the openings produced are 20 m wide, 42 m high, and 100 m long, and, in another, 20 m wide, 100 m high, and 60 m long.

To maintain stability of the rock, salt masses must also be left behind using the grid wall system, the vertical pillars being 10 – 30 m thick, and the horizontal pillars between the sublevels, 8 m thick.

Loading and Haulage. To load the mined material after blasting and to transport it to the first crusher, diesel-powered front loaders with bucket capacities of up to 18 t are used (LHD: Load, Haul, Dump System). For economic reasons, there should be a straight road between loading and discharging points not longer than ca. 300 m. For longer distances, the interrupted system is more economic, with special loading equipment and dumper trucks of up to 50 t capacity.

After crushing the salt to < 300 mm using equipment near to the working face, it is transported by band conveyors to the hoisting shaft.

In mines where the salt has a purity of > 99 % NaCl, the salt can be marketed directly after grain-size classification.

Where the natural purity is lower (e.g., 94 % NaCl in South German mines), impact mills are used in the first processing stage. As rock salt is more brittle than the clay and anhydrite inclusions, it is more readily size reduced. A screening operation follows, separating the two size fractions, which increases the NaCl content by 2 – 3 % compared to the crude salt. Further purification of the salt to > 99 % NaCl for industrial use is carried out in heavy media hydrocyclones.

Utilization of the Chambers. Salt mining is mainly carried out without back-filling, i.e., the chambers produced during mining need not be backfilled with other material to support the roof of the mine and increase the load-bearing capacity of the salt pillars.

Where processing of the rock salts produces residues that must be disposed of, these are usually dumped in the empty chambers. Hence salt mines do not produce heaps of tailings at ground level.

In some cases, empty chambers are utilized for disposing of waste materials, e.g., wastes from combustion processes and the chemical industry.

4.2. Production of Crude Brine by Mining Methods

The principle of all mining methods for the production of crude brine (NaCl solution) is the use of “wet mining”.

The rock salt, which may be present in a pure state (e.g., geologically undisturbed crystalline salt deposits) or in a mixed mineral in finely divided form (e.g., in alpine salt deposits), is dissolved by the action of fresh water on the rock formation and converted to a concentrated salt solution (brine with an NaCl content of 312 g/L or 27 %).

In all processes, the brine is produced in underground excavations made by conventional mining or solution mining [14-20]. The extraction processes result in formation of chambers [21]. Between the chambers in which the brine is produced and extracted, pillars of considerable size are left behind to maintain stability of the rock [22], [23]. Figure 3 gives a survey of brine mining methods.

Figure 3. Classification of brine mining methods

Mining of brine is no longer widely used. It is employed in alpine salt deposits and in a few rock salt mines. The most widely used and most economic process today is solution mining (see Section Controlled Solution Mining) [14], [15]. In a few cases, subsurface solution mining is also carried out at depths of 100 – 140 m [24], [25].

Water flushing (intermittent or continuous dissolution in chambers) is the extraction process usually used in the alpine salt deposits in West Germany and Austria [14], [15], [18-20]. Tunnels, shafts, and chambers are usually first produced by mining techniques. A single worked stratum is divided into separate districts of a given size in which several extraction chambers are set up. A block of definite dimensions (length, breadth, and height) is allocated to each chamber based on a predetermined degree of extraction. The block encompasses a space of irregular configuration produced by the extraction process and the pillars left between the extracted spaces, which are also of irregular shape. An initial space is first created, which is a funnel-shaped (Germany), or circular chamber (Austria). A shaft or tunnel is first driven from the main tunnel or a transverse tunnel to the center of the intended block at the bottom of the worked strata. A shaft is then sunk by mining techniques from which the initial chamber of a specific size is created at the lowest point by drilling and explosive methods (Austria). In Berchtesgaden, Germany, the initial space (Fig. 4) required for excavation is created by drilling and water-injection processes. An important feature of this process [20], [22] is that the initial space is funnel-shaped, and is generated by controlled dissolution, starting from a wide borehole, so that the insoluble components of the deposit can be raised by airlifting equipment and removed by a hydraulic pump as a solid – brine mixture. The production of the initial space is usually divided into the following stages (Fig. 4): sinking a borehole for examination of the deposit in the region to be excavated, vertical development by sinking a wide borehole, further widening of the borehole by controlled dissolution, forming a funnel-shaped space at a depth extending from 100 to 125 m. During this phase, the space normally attains a volume of 3000 – 5000 m^3, depending on the quality of the deposit, with a height of 4 – 6 m and a diameter of 30 – 32 m. The creation of the initial space completes the preparation for the extraction process. The space is next extended further, conditions now having been established for continuous, high yield, cost effective brine production. The initial space (chamber) is slowly filled with fresh water, which dissolves salt from the side walls and roof. The insoluble components, such as clay, anhydrite, and polyhalite sink to the floor of the chamber. Fresh water is continuously added, raising the liquid level, so that water remains continuously in contact with the roof of the chamber until the water in the chamber is completely saturated. The dwell time depends on the salt content of the rock, the size of the chamber, the ease of dissolution of the salt, and the surface area of the chamber roof, and is usually between 10 and 30 days. After complete saturation has been attained (312 g/L), the brine is removed either by pumping out of the excavated space (if working below the tunnel level), or by draining off to the level below. The space is then refilled with fresh water. This procedure (filling, saturation, emptying), is known as intermittent water flushing, and is repeated until the chamber roof area has reached ca. 3000 – 3200 m^2. The chamber is then ready for continuous brine production by the continuous water flushing process. The water flows at a rate appropriate for the parameters of the deposit, with simultaneous removal of concentrated brine by draining or pumping. The brine production is now almost invariably carried out below the main haulage level (Germany and Austria), i.e., working upwards from the bottom. Each day, 1 – 1.5 cm rock salt is dissolved from the surface of the roof of the chamber. The chambers take on a funnel-shaped to cylindrical configuration (Fig. 4). Chamber heights in Austria [19], [24], [25] are 20 – 30 m (normal working) or 50 – 80 m (deep working), depending on the

diameter. In Berchtesgaden, Germany, the exploitable height of the chamber is 100 m. The initial space is created in the region between 100 m and 125 m below the level of the tunnel.

Figure 4. Production of the initial extraction chamber by drilling and water flushing, and brine production operating below the main tunnel (Salzbergwerk Berchtesgaden, Germany)

To calculate the efficiency of extraction of the deposit, the salt content of the rock and the size of the rock mass assigned to the particular operation point (cavern), including the horizontal safety pillars, must be taken into account. In Berchtesgaden, Germany, when the size of the horizontal and vertical pillars, the average salt content of alpine deposits (50 %), and the usable height of the chamber (100 m) are taken into account, the total quantity of brine available per chamber is 1.1×10^6 m^3. This corresponds to an extraction efficiency of ca. 12 % [20], [22]. In Austrian salt extraction operations, the following total available quantities of brine have been quoted, depending on the type of extraction chamber [24] and [25]: 200 000 – 400 000 m^3 for normal operations, and 700 000 – 1 000 000 m^3 for deep operations.

The *work face dissolution process*, in which dissolution is carried out in chamber-like tunnel sections, is similar in principle to the intermittent water flushing process, and is also not widely used. In some mining operations in Germany and Poland [15], [17] it is still operated alongside other brine production processes (e.g., solution mining using boreholes drilled from the surface).

To obtain the brine, transverse tunnels are driven one above the other on both sides of the main tunnel (Fig. 5). The transverse tunnels are linked together at their ends by a borehole. Passing from one tunnel to the next, the borehole is widened to a shaft of 1 m diameter and provided with an outlet to the lower tunnels. About 10 m below each tunnel, a tunnel for brine production is driven from the widened borehole, a work face is produced by cutting upwards at the end, and spraying equipment is installed at that point. This creates a cut which moves backwards at a fixed height until it meets the widened borehole. After the initial work has been finished, the working is filled with water or unsaturated brine. The water or brine remains in the working until saturation is reached. The concentrated brine is then removed via the lower work face. In contrast to the water flushing process described above, the salt is only removed from the work faces until the planned chamber width is produced.

Figure 5. Production of brine work-face dissolution

a) Access tunnels; b_1) – b_3) Transverse tunnels for work faces 1 – 3; c) Borehole widened to make a shaft; d) Brine removal; e) Transverse tunnels; f_1), f_2) Spraying equipment

The production of brine by means of water jets is only used to a small extent, being employed in a few cases to solve special problems, e.g., to speed up excavation during intermittent water injection at the development stage, or to regulate the configuration of the chamber during the water flushing process in large chambers.

4.3. Controlled Solution Mining

Controlled solution mining is the modern, economical method of extracting rock salt from underground deposits, and contrasts with conventional mining (see Section Mining of Rock Salt). However, for this method certain preconditions must be fulfilled, especially with regard to the geology of the deposit (type, formation, and depth of the salt). Economic operation of the solution mining process requires that the deposit—whether a diapir (salt dome) or a flat stratum of salt—should fulfill the following geological conditions:

1. Adequate thickness and extent of the salt deposit
2. High purity of the rock salt without inclusions of potassium chloride
3. Largely undisturbed stratification at medium depth

In addition, an adequate supply of water must be available.

4.3.1. *Drilling and Construction of the Borehole*

The drilling and completion of the trial boring and the design and installation of the brine wells (also known as the cavern wells) closely resemble those of petroleum and natural gas wells (see ⟶ Oil and Gas). The method of operation and the geological conditions determine the size, type, and position of the casing that protects the walls of the borehole against the effects of permeable strata, and prevents solid material from the rock from falling into the borehole. A standard pattern for the casing diameters in a cavern well (see Fig. 6) is as follows:

1. 0 – 15 m: 24.5 inch pipe
2. 0 – 300 m: 16 inch pipe
3. 0 – 20 m (max.) beyond the projected roof of the cavern in the deposit: 11.75 inch pipe

Figure 6. Method of brine production

The casings described in 2) and 3) above are cemented up to ground level.

Geophysical borehole measurements and tests on the cores obtained during sinking of the borehole not only give information about mineralogical composition, but also yield physical data about the overlying rock and the salt deposit. The most important characteristics of the overlying rock are its thickness and strength. Also, to enable the dimensions of the cavern and the proposed extraction process to be decided upon, the strength and thickness of the salt deposit and the solubilities of its component parts must be known.

The outer casing must be installed and cemented with special care, and each individual joint as well as the whole casing must be tested for tightness. After this, the well is completed by inserting two concentric pipes (of diameter between 8.625 and 5.5 inches), the final preparative work being the assembly of the well head and making all the pipe connections (Fig. 6).

4.3.2. *The Process of Solution Mining*

As shown in Figure 6, fresh water is pumped into the borehole through the annular space between the two inner pipes. The water dissolves salt from the walls of the cavern. The solution sinks as its salt content increases, and the saturated brine formed then rises to the surface in the central pipe due to the applied pressure.

Dissolution of salt from the roof is prevented by injecting a protective liquid or gas blanket through the annular space between the outer casing and the pipe carrying the fresh water. This blanket forms a layer above the water due to its lower density, so protecting the roof. Insoluble materials collect at the bottom of the cavern.

The desired cavern shape is produced by stepwise adjustments to the depth of the water-injection pipe and the level of the blanket [26-29].

The extraction process is controlled by continuously measuring the salt content of the brine, the blanket pressure, and the quantity of brine extracted. The cavern space produced is calculated from these data by computer, and the spatial extent of the cavern is continuously determined by echometric surveying. The actual cavern produced can then be continuously compared with the planned cavern.

4.3.3. *Planning of the Extraction Process*

The safety of caverns can be ensured if pillars of adequate width are left between neighboring caverns and if there is a thick enough mass of solid salt at the top of each cavern. The width of the pillar and the thickness of the roof depend on the planned cavern dimensions, the cavern shape, and, in particular, on the mechanical properties of the salt deposit. The latter have been investigated in detail [29-35].

Furthermore, correlations and formulas have been derived that enable the forces produced in the rock to be calculated from the size and shape of the cavern, the interior pressure produced by the solution mining process or subsequent use for storage purposes, the depth and thickness of the overlying rock, and the mechanical properties of the surrounding rock formations. The decrease in the volume of large caverns (convergence) caused by elastoplastic properties of the rock salt are determined from formulas, confirmed by data from practical experience [30-39].

Irrespective of the widths of the pillars calculated with these equations, the wells in a brine field should be arranged in a hexagonal pattern (Fig. 7), which gives optimum utilization of the available area.

Figure 7. Hexagonal arrangement of caverns in a brine field with a level salt deposit

a) Cavern (diameter*D* = 60 – 100 m); b) Borehole; c) Pillar of stable rock salt (thickness of pillar: 2 *D*); d) Upper layer of anhydrite

The distance between the brine wells is the sum of pillar width, the maximum cavern diameter, and a safety factor to allow for deviation of the borehole from the vertical. If a borehole must be relocated due to the situation at ground level, the hexagonal arrangement below ground can be maintained by adjusting the drilling direction (Fig. 8).

Figure 8. Directional drilling in the production of a cavern

4.3.4. *Other Systems*

Individual boreholes for extracting brine can generally only be operated economically in thick salt deposits or salt domes. However, thin salt deposits can also be exploited economically in some cases. Here, two or three boreholes are linked together by injecting water to dissolve the salt and to fracture it by hydraulic action [28], [40], [41]. Fresh water enters via the first borehole, and the brine is collected from the second or last borehole. Here also, dissolution of the roof is prevented by a blanketing medium. The floor is dissolved first, then the roof. With thin seams of salt, the strength and impermeability of the overlying strata are very important.

Control of this method of solution mining is more difficult than with individual brine wells. The stability of the cavern spaces cannot be guaranteed, as there is a risk of uncontrolled dissolution processes. Thus, this method of solution mining is only used in countries with few salt deposits where there are sparsely populated areas above thin salt strata.

4.3.5. *Equipment*

The equipment requirements normally consist of

1. Equipment for supplying water, sometimes including a pipeline
2. A pumping station with a distribution system delivering water to the individual solution mining operations
3. A pipeline for transporting the brine to the consumers
4. A central system for supervising and controlling the entire processing equipment

The water is injected by high-pressure centrifugal pumps at a pressure determined by the difference in the densities of the two media (water and brine) and the friction losses in the pipes. The salt at the working face dissolves and passes through the central pipe as saturated brine to the well head and into the piping system. The low residual brine pressure at this point is sufficient to deliver it to the pumping station, where delivery pumps force the brine into the pipeline that takes it to the consumer industries.

4.3.6. *Storage Caverns*

The caverns remaining after extraction of the sodium chloride can be used for storage of mineral oil, mineral oil products, and gases such as natural gas and ethylene.

Emergency reserves of mineral oil or mineral oil products can be injected through a pipeline into the brine-filled caverns by a high-pressure pump. In place of the two concentric pipes used in solution mining, a brine removal pipe is suspended in the cavern with its open end just above the sump region. The mineral oil is forced into the annular space between the outer pipe and the brine removal pipe and displaces the brine, which rises through the brine removal pipe to the surface and is fed into the brine network, and thence to the production plant. To discharge the oil, the process is reversed.

Caverns in rock salt are also suitable for gas storage. For example, natural gas is stored to compensate for seasonal and daily variations in demand. The conversion of a cavern to a gas-storage system is more complex than conversion to liquid storage. To protect the outer piping against pressure and temperature variations during operation, a protective pipe is fitted. The annular space between this pipe and the outer pipe is pressurized so that the welded pipes are under a constant load. For the first filling operation with gas, a brine extraction pipe is lowered to the bottom of the cavern. The gas in the annular space between the protective pipe and the vertical central pipe is compressed to a high pressure, and displaces the brine from the cavern until the latter is completely empty. The gas storage system operates by the principle of compression-decompression. The gas in the cavern required to maintain the minimum residual pressure required for stability of the cavern is called the cushion gas, but when it is filled up to its maximum operating pressure, it is known as the working gas.

Descriptions of cavern storage systems can be found in [42-45]. A worldwide information exchange service is provided by the Solution Mining Research Institute (SMRI), Woodstock, Illinois.

4.4. Production of Sea Salt

Introduction. In his *Historia Naturalis*, PLINY THE ELDER already referred to the technique of producing salt by the natural evaporation of sea water. Even today, this method of exploiting the oceans, seas, salt lakes, and chotts is still widespread. It is practiced in nearly all regions of the world where climate and topography allow.

While some methods have changed very little, such as those of the “Paludiers” working the salt marshes along the Atlantic coast of Portugal and France, other modern methods are now applied, combining productivity with strict environmental protection. This applies to the vast majority of salt fields in the Mediterranean basin, on the west coast of Australia, and Guerrero Negro, the world's largest salt field in Mexico at the southernmost tip of Baja California.

4.4.1. *The Raw Material: Sea Water*

The water of the seas and oceans contains all the known elements, most of them present in small amounts [46]. Sodium chloride is the most important compound in terms of concentration, averaging 28 g/L.

Sea water also contains significant amounts of magnesium, sulfur, and calcium, the other important sea-water-based process being the production of magnesium compounds.

The salinity (grams of salt per kilogram of sea water) of ocean and sea water varies with location and depth [47]. This dispersion, due either to dilution by precipitation or drainage pattern, or to local overconcentration caused by strong evaporation, is more evident in inland seas.

The average salinity is 3.5 %, corresponding to a relative density of 1.026. It reaches 4.1 % in the Red Sea and is only 3 % in the Baltic Sea.

The salt mixture in sea water has the following typical composition (in wt %) [47]:

NaCl	77
$MgCl_2$	10
$MgSO_4$	6
$CaSO_4$	3.9
KCl	2

4.4.2. *The Main Factors Governing Production of Sea Salt*

To produce sea salt economically, the amount of water evaporating must exceed the amount of precipitation (rain or dew) for a long and continuous period of at least three months during the year.

Table 5 lists the main types of climate compatible with the production of sea salt. In Taiwan, a borderline case, sea salt production calls for a maximum of ingenuity. In Western Australia, by contrast, the climate is ideal, notwithstanding the risk of cyclones, and sea salt can be produced all year round.

Table 5. Typical climatology of solar saltfields [47]

	South of France	Australia	Indonesia	Taiwan
Annual evaporation *, mm	1700	3600	1850	1660
Annual rainfall, mm	550	300	1300	1400

* Fresh water.

In practice, evaporation at a given production site is measured over fresh water with an evaporometer. Since the total concentration of dissolved salts is known, the evaporation is determined approximately from an empirical curve, an example of which is shown in Figure 9 [48].

Figure 9. Evaporation coefficient α as a function of density

1 cm of evaporation over fresh water corresponds to α cm for the body of water in question; α normally ranges from 0.95 for sea water to 0.55 for saturated brines depositing their salt.

In addition to a favorable climate, a particular topography is required, and the ground must be as impermeable as possible to minimize brine seepage.

The pond areas containing the brines or saline solutions must also be as level as possible, ideally below sea level, and stepped in elevation. This reduces the number of intermediate pumping stations required and helps to optimize the design of the ponds, dikes, channels, and culverts making up the salt field.

These conditions are often satisfied in the deltas of large rivers. The Rhône delta in France's Camargue is one example, and is the location of two large salt fields: Aigues-Mortes and Salin de Giraud.

Concentration of Sea Brines. After being pumped from the sea, the sea water passes through the salt field from pond to pond. As it passes through the ponds, the NaCl concentration in the sea water rises from 28 g/L to roughly 260 g/L, corresponding to an increase in relative density from 1.026 to 1.215. At this point, the brine begins to deposit its salt. Most

of the calcium carbonate ($CaCO_3$) and calcium sulfate ($CaSO_4 \cdot 2\ H_2O$) has already crystallized before this point, as shown in Figure 10, while the magnesium salts continue to become concentrated without crystallizing.

Figure 10. Brine composition as a function of density [49]

Values for $CaSO_4$ concentration are multiplied by a factor of ten.

Crystallization of Sodium Chloride. When the brines approach the NaCl saturation point, they are fed through feed channels into the crystallizers, which represent the production units. The floors of the crystallizers must first be carefully prepared by compacting and levelling to ensure easy separation of the salt from the ground and a uniform layer of brine. The surface area of these crystallizers generally represents ca. 10 % of the total area of the salt field.

From this point on, the salt worker's job is to monitor the brine strengths and purge the bitterns from the ponds when the concentration of secondary salts, particularly magnesium salts, is liable to lower the quality of the salt. The ponds are then filled with fresh or pure brine with a low magnesium salt content.

The salt is produced in the form of a layer of tangled crystals whose density and grain size depend on the characteristics of the bittern and, especially, on the turbidity or cloudiness. If the brine is turbid, the suspended fine particles act as seed crystals. If, however, the brine is clear and well settled, the number of seed crystals is greatly reduced, and crystal growth occurs in preference to germination.

The thickness of the salt layer varies from one site to another, and also, at a given site, from one year to another, depending on weather conditions. In the South of France where the production period runs from May to September, the thickness at the end of the season averages 10 cm. At other latitudes, layers may be over 20 cm thick.

4.4.3. *Production Stages in a Modern Salt Field*

Figure 11 shows the main components of the infrastructure of a modern salt field, from sea water intake to the production facilities for processing and packaging the salt.

Figure 11. Modern salt field [47]

a) Sea water intake; b) Pumping station; c) Dikes; d) Condensers; e) Brine storage tanks; f) Crystallizers; g) Bitterns area; h) Washing plant; i) Salt storage areas; j) Packaging plant; k) Dispatch

The production process features the following stages:

1. Seawater pumping: the salt field is supplied with sea water by a pumping station. In some parts of the world, such as Australia, the salt fields are gravity fed with sea water in accordance with the tides. Several million cubic meters of sea water are required annually to produce several hundred thousand tonnes of sodium chloride (the Aigues-Mortes salt field in France pumps $50 \times 10^6\ m^3$ of sea water for an average annual output of 400 000 t).
2. Concentration of sea water in the ponds: in this stage, the water flows through shallow ponds and is allowed to concentrate until approximately 90 % of the initial water content has evaporated. The brines are moved pond to pond by gravity or by pumping as dictated by the local topography.
3. Deposition of NaCl in the crystallizers: for a salt field with a single production season during the year, the crystallizers are first filled with brine kept from the previous year, which has been protected from rain dilution in deep storage ponds. A few weeks later, the old brine is replaced by the new concentrated brine leaving the ponds.
   By the time the relative density of the brine reaches 1.215, when NaCl crystals start to form, the brine has already precipitated 80 % of the calcium sulfate in the form of gypsum. The bitterns are then removed before the specific density reaches 1.260 to avoid codeposition of magnesium salts. Where bitterns are present in sufficiently large quantities, and if the climate allows, the bitterns can be concentrated on a bittern salt field to extract the magnesium bromide, magnesium sulfate, and even magnesium chloride (⟶ Magnesium Compounds).
4. Salt harvesting: in batch-operated salt fields, salt harvesting begins at the end of the salt production period. For continuous salt fields, harvesting is performed at regular intervals to ensure that the level of the salt does not exceed the operating height of the harvesting machines.
   The harvester is generally carried by a tractor of the type often used for civil engineering projects. The salt is first scooped off the floor of the crystallizer by a large blade up to 3.6 m wide pushed along by the tractor. It is then lifted by slotted or bucket conveyors. The salt is then evacuated and poured into trailers by a conveyor belt.
5. Transport, washing, and storage: the harvested salt is loaded onto trucks or tractor-drawn trailers for transport to a washing plant where most of the impurities are removed.
   Washing removes all solid impurities from the salt (substances insoluble in water) along with the accompanying bitterns (solutions of magnesium or potassium compounds). The salt is kept in suspension in saturated brine. The salt – brine mixture is then dewatered and centrifuged. The salt travels up an inclined gantry conveyor and is poured on top of one of the huge salt stockpiles that are a familiar feature of salt production sites.
6. Processing and packaging: The salt reclaimed from the salt stockpile may be washed a second time, which

increases the sodium chloride content to 99 %. The salt is then generally dried, crushed, and screened, and anticaking agents are added. Other substances added at this stage include iodide or fluoride in salt for human consumption. The salt is then packaged in various containers (e.g., boxes, polyethylene bags), as required by the consumer.

[Top of Page]

5. Production of Pure Salt by Evaporation of Brine

Georg Steinhauser

Salt can be produced by evaporation of saturated brine (for brine production, see Sections Production of Crude Brine by Mining Methods and Controlled Solution Mining). Brine is generally obtained by dissolving crude salt that contains many impurities. The production of high-purity salt requires chemical purification of the brine. The high purity is the major difference to rock salt (see Table 6). Purification is also necessary to avoid scale formation in the heat exchangers and the evaporation equipment. Additionally, the use of pure salt in industrial processes causes much less waste than the use of rock salt. On the other hand, the purification of salt itself causes wastes, because of the foreign ions in the crude salt.

A summary of possible processes for the production of salt is shown in Figure 12.

Figure 12. Processes for the production of salt (after [72])

5.1. Purification of Crude Brine

Brine purification is an important step in the production of sodium chloride for industrial purposes and nutrition. Magnesium and calcium ions must be removed from the saturated sodium chloride brine to avoid scale formation and also impurities such as hygroscopic magnesium chloride in solid sodium chloride.

On the other hand, these ions must be removed for several technical reasons, e.g., for membrane chlorine-alkali electrolysis. In the Solvay process, brine purification is essential as well (see ⟶ Sodium Carbonates – Technology). During carbonization they would form scales such as basic and neutral carbonates or the triple salt Northupite, $NaCl \cdot MgCO_3 \cdot Na_2CO_3$ [73] or $2\ MgCO_3 \cdot 2\ Na_2CO_3 \cdot 2\ NaCl$ [74], in the production units and therefore cause damage.

The most common and most problematic impurities in crude salt are the sulfates, chlorides, and, to some extent, the carbonates of calcium and magnesium, and the triple salt polyhalite ($K_2SO_4 \cdot 2\ CaSO_4 \cdot MgSO_4 \cdot 2\ H_2O$), but also the water which is used for dissolving rock salt contributes to the content of impurities in the crude brine. Most of the magnesium compounds are very soluble in crude brine. Furthermore, the crude brine is saturated with calcium sulfate in many cases. Sodium chloride brine significantly enhances the solubility of calcium sulfate [75]. This effect is called “salting-

in".

The principal impurities of crude brine are therefore calcium, magnesium, and sulfate ions, but also strontium ions (usually dissolved in relatively low concentrations in crude brine; see Table 10), all of which take part in scale formation. Potassium ions are irrelevant for the formation of incrustations in the evaporation equipment due to their high solubility. They only play a role as impurities in the final high-purity product [76].

* Concentrations at 14 °C.
** The combined concentration of Mg^{2+} and Ca^{2+} must be < 20 ppb.

The following chemical methods are used to purify crude brine [50].

Purification with Lime or Caustic Soda and Soda Ash. Traditional brine purification is performed in the Schweizerhalle process, named after a Swiss saline. It consists of two steps:

1. Addition of calcium hydroxide to precipitate magnesium ions as magnesium hydroxide and produce gypsum due to the increase in the concentration of calcium ions in a solution already saturated with calcium sulfate:

   $$Mg^{2+} + SO_4^{2-} + Ca(OH)_2 \rightarrow Mg(OH)_2 + CaSO_4$$

   Usually, solid calcium oxide is preferred over milk of lime, because it does not dilute the saturated sodium chloride solution further. Since lime is hydrated much more slowly in brine than in water, it is important to use highly reactive, fine-grained lime. However, if a higher degree of utilization of the calcium oxide is desired, milk of lime with a content of about 20 % calcium oxide can be used as well [76]. Where cheap sodium hydroxide is available, it can be used instead of calcium hydroxide, thus avoiding additional input of calcium ions. In this step, an excess of base is always added to reach a pH of about 11.3.
2. The addition of soda ash to precipitate the remaining calcium ions as calcium carbonate:

   $$Ca^{2+} + Na_2CO_3 \rightarrow CaCO_3 + 2\,Na^+$$

   The crystallization of calcium carbonate can also be achieved by purging the alkaline brine with carbon dioxide, easily available in the form of combustion gas, which contains about 10 – 14 vol % carbon dioxide. Although a minimum concentration of dissolved calcium ions is obtained at a pH of about 9.5, purging is usually stopped at a pH of approximately 11.2, thus avoiding the formation of soluble calcium hydrogencarbonate, which can hardly be removed [76].

After these two reactions, magnesium and calcium ions are removed almost quantitatively (see Table 10). The insoluble compounds are decanted and filtered after each purification step. The resulting basic sludge is generally considered to be useless and is therefore suspended in water and pumped back into abandoned caverns of the salt mine, or washed into rivers, lakes, or the sea. There it covers the ground and thus may threaten the equilibrium of the aquatic ecosystem.

A typical value for the amount of sludge is 15 kg per m^3 of crude brine or 50 – 55 kg per ton of evaporated salt. In Austria, for example, the composition of the water- and salt-free brine purification mud is 58.8 % calcium sulfate, 23.4 % calcium carbonate, 16.8 % magnesium hydroxide, and 1.0 % clay minerals, which are impurities of the limestone [77].

Recently, the use of this sludge as a lime fertilizer has been discussed [77-79]. However, three aspects must be considered:

1. The brine purification mud must be washed thoroughly to remove most of the chloride. A fertilizer should contain < 1 % chloride [79].
2. The sludge must have a sufficiently low water content (≤ 28 wt %) if conventional fertilizer-distributing machines are to be used [79].
3. Such fertilizer does not contain significant amounts of the three major macronutrients nitrogen, phosphorus, and potassium. Earlier studies on the growth of plants on similar wastes show that growth is limited primarily by the low content of phosphorus [80].

Sulfate is not removed completely from the crude brine in this purification process. Salt is obtained from the purified brine by evaporation, which is stopped prior to the onset of sodium sulfate crystallization. The residual solution is called “mother liquor” and contains sodium and potassium chloride, sulfate, and carbonate (due to the excess of soda ash in the second reaction; see Table 10). The saturation concentration of sulfate depends on the composition of the purified brine, but normally the value is about 48 g of sodium sulfate per kilogram of mother liquor. Brine with a higher potassium content allows a higher sulfate concentration in the mother liquor without crystallization of an alkali metal sulfate [76]. After removing the mother liquor, it can be fed to an expansion evaporator, where a second fraction of pure sodium chloride can be produced with an extent about 50 kg of sodium chloride per cubic meter of mother liquor. The residual solution can be used for the production of sodium sulfate, or, in combination with purified brine, for the production of soda ash, where sodium sulfate is also an appropriate sodium source. Since a high sulfate concentration in the brine for the Solvay process causes formation of gypsum scales during the recovery of ammonia with milk of lime (see ⟶ Sodium Carbonates – Technology), this strategy is not entirely unproblematic.

Purification in a Circulating System. Here, the brine is usually treated in two stages. In the first stage, crude brine, mother liquor, and calcium hydroxide suspension or sodium hydroxide solution are thoroughly mixed. This causes magnesium hydroxide, calcium sulfate, and a little calcium carbonate to precipitate. The crystallization of calcium carbonate is caused by the content of carbonate ions in the mother liquor. It is also formed if the crude brine contains hydrogencarbonate ions, due to the following equilibrium:

$$HCO_3^- + OH^- \rightleftarrows CO_3^{2-} + H_2O.$$

Other problematic metal ions are precipitated in addition to the alkaline earth metal ions. After removal of these solids, sodium hydroxide solution and/or sodium carbonate solution are sometimes added to the clear brine, which is saturated with calcium hydroxide, in the second stage. Additionally, carbon dioxide (usually in the form of combustion gas) is blown through, whereby calcium carbonate crystallizes and is removed. The clarified brine is fed to the evaporator and evaporated until sodium sulfate just fails to crystallize. The salt is recovered, the major part of the mother liquor (more than 80 %) is recycled to the first stage of the brine purification process, and the residue must be disposed of if it can not be made use of in a way described above. In practice the ratio between mother liquor and pure brine is about 1:5.

Split-Precipitation. A novel process [81, 82], property of Solvay S.A., can help make brine purification more ecologically acceptable by reducing the amount of brine purification mud. Instead of substituting magnesium by calcium ions, the first step is adding soda ash to the crude brine:

$$Mg^{2+} + Ca^{2+} + 2\,Na_2CO_3 \rightarrow MgCO_3 + CaCO_3 + 4\,Na^+$$

“$MgCO_3$” is the simplified notation for “basic magnesium carbonate” (“magnesia alba”), nonstoichiometric formula 4 $MgCO_3 \cdot Mg(OH)_2 \cdot 4$ or 5 H_2O [83] or 5 $MgO \cdot 4\,CO_2 \cdot x\,H_2O$ (x = 5 – 12) [84].

A certain percentage of magnesium ions is removed in the form of basic magnesium carbonate in this reaction and need not be precipitated with calcium hydroxide. This helps save milk of lime and furthermore reduces the input of calcium ions and consequently the amount of sludge. However, magnesium cannot be removed quantitatively in this step due to the solubility of precipitated (basic) magnesium carbonate in concentrated sodium chloride brine.

Therefore, in the next reaction milk of lime and, if used, mother liquor (“SO_4^{2-}”), are added to the brine to remove the remaining magnesium ions:

$$Mg^{2+} + SO_4^{2-} + Ca(OH)_2 \rightarrow Mg(OH)_2 + CaSO_4$$

Of course calcium carbonate is precipitated in this reaction as well, because of the remaining carbonate ions dissolved in the brine. In the final reaction calcium ions are precipitated in the traditional process using sodium carbonate. The precipitates are removed from the brine by decantation and/or filtration after each purification step. Before the sludge is disposed of into the waters, it is suspended in water and thoroughly stirred. Basic magnesium carbonate (coming from the first reaction) and calcium sulfate (coming from the second reaction) react within a short time:

$$MgCO_3 + CaSO_4 \rightarrow MgSO_4(aq.) + CaCO_3$$

This reaction is accelerated by remaining sodium chloride in the slurry [85].

Result: one solid, namely calcium carbonate (instead of two) and magnesium sulfate (soluble and nontoxic).

The resulting magnesium sulfate solution is diluted in the water and does not accumulate on the ground like the sludge. Especially if the waste waters are disposed of into the sea, the magnesium sulfate solution is of no ecological significance.

Since magnesium ions are removed from the crude brine in two different steps, this process was called Split-Precipitation. This process, especially the final step, helps reduce the volume of sludge by approximately 30 wt % compared with traditional brine purification, the quality of the purified brine staying the same. The reduction of the amount of mud is the main (ecological) advantage. If the extent of sodium chloride or soda ash production is legally regulated, limiting the amount of waste sludge, this process helps increase production.

The composition of the sludge is another ecological advantage: The main constituent is no longer gypsum, but about 50 % calcium carbonate, which is almost identical with the sediments in alpine regions. Less basic magnesium hydroxide is produced and washed into the waters, which is a further ecological advantage of this novel process.

Furthermore, if this process is used for the Solvay process, it must be kept in mind that soda ash production generates large amounts of calcium chloride wastewaters. The wastewaters of this novel brine purification process contain dissolved magnesium ions. Since calcium and magnesium are biological antagonists, the natural Ca/Mg equilibrium is partly restored.

Split-Precipitation causes only a very small increase in soda ash consumption, which is the main cost factor in brine purification, so it appears to be cost-efficient.

Design of Brine Purification Plants. The brine purification processes described above were formerly carried out as batch operations, but today continuous processes are more common. Continuous processes require an almost constant composition of the crude brine. On the other hand, they use smaller reactor vessels than batch processes. In both methods, the impurities are allowed to settle and are then removed. Sedimentation is accelerated by adding flocculating agents, usually anionic polyacrylates Flocculants – Chemical Structure and Flocculants – Uses. In the continuous process, the solid precipitates are removed in thickeners. Thus, the whole process consists of three stages:

1. Mixing with flocculants
2. Flocculation stabilization
3. Sedimentation and decantation of the solids

Continuous brine purification can be carried out in one reactor vessel as well [76]. In this case, the conical vessel is filled with crude brine and mother liquor from the bottom and milk of lime from the top. The formation of gypsum causes caustification. Sodium hydrogencarbonate is added and, due to the equilibrium with hydroxide ions, carbonate ions are formed, which precipitate calcium carbonate. The precipitates settle, and clarified brine is taken from the top. The resulting sludge contains about 60 % solids and is removed from the bottom. The main disadvantage of this process is that the brine has to be kept at a temperature between 80 and 100 °C.

Quality of the Purified Brine. Purified brine still contains low concentrations of problematic ions [76] (Table 10).

A minimum concentration of magnesium ions in brine is reached with a hydroxide concentration of about 0.003 mol/L in the brine. The solubility of calcium and strontium ions is temperature-dependent. Soda ash is usually used with 0.003 – 0.004 mol/L in excess.

The low-concentration alkaline earth metals in the purified brine form primarily carbonate scales in the evaporators, with the following composition: 71.5 % calcium carbonate, 22.2 % strontium carbonate, 2.1 % magnesium carbonate. These carbonate incrustations must be removed with acids. To avoid this problem, ion exchangers can be used to remove the remaining alkaline earth metal ions. This strategy is mainly used for the production of ultrapure brine for membrane chlorine-alkali electrolysis (for some limit values, see Table 10 and ⟶ Chlorine – Brine Purification).

Another method is keeping these ions dissolved by using complexing additives, usually polyphosphates or phosphonates. Such antiscalants prevent the formation of insoluble carbonates. The alkaline earth metal ions then accumulate in the mother liquor [76].

For the production of food-grade salt, the purified brine is filtered after the purification process to remove very small particles.

5.2. Evaporation of Brine

In an evaporative crystallizer, the salt normally crystallizes at 50 – 150 °C, the solubility of sodium chloride increasing only slightly with temperature (see Table 1). In the majority of cases purified brine is evaporated. Crude brine can be used for the production of industrial salt by the gypsum slurry process, in which a certain quantity of crystalline calcium sulfate hemihydrate is maintained in the suspension of salt crystals. Calcium sulfate precipitates deposits on these hemihydrate crystals and hence scale formation on the heating surfaces or the walls of the vessel is reduced. It was found helpful to raise the operating temperature to 150 °C when utilizing this process to prevent scale [88].

Salt was formerly produced by evaporation in open pans. Due to the high heat consumption and relatively poor performance, this method is meanwhile only used for the production of special sodium chloride products [50], [51]. These pans have an evaporation area of up to 180 m^2. In Germany, one saline, Luisenhall, probably the last one in Europe, still uses this method. Evaporation in open pans has the advantage that brine purification is not absolutely essential. This method of evaporation takes place at a temperature of about 85 °C and produces large, hollow pyramidal crystals [72], [76].

Heat is used most efficiently in multistage evaporation and vapor recompression processes Evaporation – Types of Evaporators and their Energy Consumption. Multistage evaporation units Evaporation – Multistage Evaporation always produce finer grained salt, they are robust and uncomplicated in operation, but their construction is expensive and their cooling water consumption high. For newly constructed plants, this type of evaporator is only economic with a volume of production of at least 80 – 100 t/h [78].

In the multistage evaporation process, heat is used more efficiently by compressing the vapors from the first evaporator to heat the second one. The pressure above the liquid decreases from unit to unit. The brine is preheated in preheaters which are heated with vapor and condensate from the previous evaporation unit. Three to seven stages can be used, but normally a multistage evaporation facility consists of five or six stages [72].

The heat of the vapor can be used in the same evaporator if the vapor is compressed to a higher pressure Evaporation – Evaporation with Vapor Recompression [52]. This vapor recompression system is widely used where cheap electrical energy is available. In this case, only one evaporator is required.

Hybrid systems are also used, which can be operated in multistage or vapor- compression evaporators [89], [90]. There are also combined methods in which high-pressure steam is passed through backpressure turbines, and the exhaust steam heats a multistage evaporation plant. The mechanical power is available for compressing the vapors.

In general, three types of crystallizers are used [53], [54]:

Type 1: Evaporators with forced circulation and external heating (see ⟶ Evaporation – Designing Evaporators for Fabrication, Fig. 11, type B)

Type 2: Evaporators with internal heaters and a circulating pump in the central pipe producing forced circulation (see ⟶ Evaporation – Designing Evaporators for Fabrication, Fig. 11, type A).

Type 3: Oslo crystallizers (Fig. 13)

Figure 13. Oslo evaporator

a) Heat exchanger; b) Vacuum evaporator; c) Down pipe; d) Crystallizer; e) Bed of crystals

In Oslo crystallizers, recirculating brine and fresh brine are heated in the heat exchanger and evaporated in the evaporator. The supersaturated crystal-free brine passes down the central pipe into the crystallizer, and from there passes upwards through the bed of crystals.

The choice of crystallizer depends on the desired crystal size. If crystal size is not important, Type 1 crystallizers are generally used. These produce cubic crystals with 50 % > 400 µm (sieve analysis). If somewhat coarser salt is desired, Type 2 crystallizers are used, giving cubic crystals with rounded corners, with 50 % > 650 µm (sieve analysis). Type 3 crystallizers produce a granular product, with lenticular or spherical particles, about 1 – 2 mm in size. Evaporation in open pans produces the largest, hollow pyramidal crystals with an edge length of up to 24 mm.

5.3. Recrystallization

The International Recrystallizer process takes advantage of the fact that the solubility of calcium sulfate in brine decreases with increasing temperature, while that of sodium chloride increases slightly. The process is applicable when solid raw material like rock salt, solar, or waste salt is to be refined to obtain a fairly pure product [50], [55].

The process consists of three stages:

1. Dissolution: Crude salt is heated with brine, which is a kind of mother liquor of this process, from the evaporator to about 105 °C in a dissolving vessel by passing steam into it, which condenses in the brine. The sodium chloride dissolves, but not the calcium sulfate, because this mother liquor is already saturated with calcium sulfate.
2. Filtration: Removal of calcium sulfate crystals and other solid impurities from the brine.
3. Crystallization: The clear brine is pumped to the crystallizer, which is a flash evaporator with forced circulation but without heaters. On expansion in this evaporator, evaporation and cooling take place. This causes sodium chloride to crystallize. On cooling, the mother liquor becomes subsaturated with respect to calcium sulfate, so that pure sodium chloride is produced. The salt suspension is removed from the evaporator, and the mother liquor is returned to the dissolution vessels. Only trace amounts of calcium sulfate appear on the salt crystals, due to mother liquor that has dried on their surface. By washing the filter cake before drying, the content of calcium sulfate in the final product can be decreased to less than 5 ppm.

Heat exchangers are generally not used in this process, which can be carried out in one or several stages.

The principal advantages of recrystallization are as follows:

1. Low steam consumption per ton of sodium chloride
2. Production of a fairly high purity product
3. Low initial costs

5.4. Other Process Steps

Manufacture of Special Salt Crystals. Salt crystals with special shapes can be produced by adding substances to the brine that affect crystal growth in the evaporation equipment. The addition of soluble hexacyanoferrate(II) complexes in amounts of about 10 mg/kg produces dendritic crystals. This salt has a very low bulk density of ca. 0.8 g/cm^3. Other suitable additives include nitrilotriacetic acid trisodium salt, nitrilotriacetamide, nitrilotripropionamide, sodium hexametaphosphate, and cadmium chloride [56], [57].

Coarse salt is also produced by compressing fine salt to form tablets or briquettes, or into compacted sheets that are then broken up to form coarsely granular salt [50].

Construction Materials. In plants producing food-grade salt, corrosion [50], [58], and therefore contamination of the product must be avoided under all circumstances. Thus, for newly built plants high installation costs are accepted rather than high maintenance costs. In this case, noble materials like 316L stainless steel are used not only for the construction of the main equipment but also for pumps, pipes, valves, and instrumentation. Other materials which can be used are: Monel (nickel – copper) alloy plated steel (especially for the evaporator itself), titanium and titanium alloys, and copper – nickel alloys (both used for the heat exchanger tubes). Rubber or plastic linings can also be used, especially poly (vinylidene fluoride) (K. F. Polymer).

Removal, Washing, and Drying of the Crystals. The crystal suspension is removed from the bottom of the conical evaporators. To completely remove the sulfate-containing mother liquor, which is purged continuously, the crystals are washed with purified brine, which enters the evaporator at the bottom, or in a pusher centrifuge. Hydrocyclones (⟶ Hydrocyclones) or decanters are used to separate the salt crystals from the solution before centrifuging [78]. If washing is not required, a screw centrifuge can be used as well. After centrifuging, the salt still contains ca. 2 – 3 % moisture. Further drying can be carried out in rotary driers, but pneumatic conveying systems using hot air or fluidized-bed driers are now more common (see ⟶ Drying of Solid Materials – Drying Methods and Dryer Types). At the end of the fluidized-bed dryer there is usually a cooling zone into which cold air is blown, or a separate cooler can be used. The dried salt is often passed through a classification process.

5.5. Salt Quality

Typical analyses of salt produced by evaporation of crude and purified brine are given in Table 7. Anticaking agents are added to the salt, such as sodium, potassium, or calcium hexacyanoferrate(II) in a concentration of 5 – 15 mg/kg, or free-flow agents like finely grinded calcium and magnesium carbonate, sodium silicoaluminate, silicon dioxide, or calcium silicate. Sometimes both types of anticaking agents are combined. Purity requirements for salt are continually increasing, especially for industrial applications such as chlorine-alkali electrolysis.

Table 7. Typical analyses of salt from evaporation processes

	From crude brine [50]	From purified brine
NaCl, %	99.7	99.95
SO_4^{2-}, mg/kg	1900	300
Ca^{2+}, mg/kg	900	7
Mg^{2+}, mg/kg	20	0.5

6. Economic Aspects

Georg Steinhauser

6.1. Commercial Grades

6.1.1. *Salt for Food.*

Salt intended for human consumption is known as cooking salt or table salt. Apart from its function as a seasoning in foods, it is of vital importance for the human organism. The average daily salt requirement for humans is 6 g [91]. In Germany, the fraction of total salt consumption used for food is only approximately 3 %. In 2003, the consumption of table salt was about 420 000 t. The largest use in the food industry is for food preservation. Only ca. 100 000 t is sold in small packages for household use [59], [92].

Caking of table salt is prevented by adding anticaking agents (see Section Salt Quality).

Table salt is used as a carrier for various active substances. Iodized table salt is important worldwide in the prevention of diseases of the thyroid gland. Fluoridated table salt is used to prevent tooth decay. A water-soluble fluoride is used for fluoridation. In Germany, only iodate is permitted for iodization of salt. In many other countries iodide is also accredited. However, both ions are equal with respect to their physiological properties. The amount of iodine added to the salt varies from country to country: in Germany, for example, 15 – 25 mg iodine per kilogram of salt is added [91], whereas in

Switzerland the amount is 20 – 30 mg iodine per kilogram of salt. In both countries, a maximum of 250 mg fluoride is added to fluoridate one kilogram of salt.

Iodization and fluoridation are performed by spraying a concentrated solution of the particular sodium or potassium salt over the crystalline sodium chloride and thorough mixing. This process can be carried out continuously or as a batch operation. Usually drying is not necessary, since one tonne of salt is sprayed with only about one liter of solution [93].

In Europe, ca. 80 – 90 % of all meat products are preserved with nitrite pickling salt, which consists of sodium chloride and various amounts of sodium nitrite [59]. In Germany, 0.4 – 0.5 % sodium nitrite is added [94]. Due to the combination with salt, nitrite can hardly be overdosed, because then the meat product would become too salty.

6.1.2. *Treated Salt*

Salt that is used neither as a foodstuff nor for the chemical industry is denatured in many countries for tax reasons. The consumption of this type of salt in Germany in 2003 was about 700 000 t.

Salt that is not suitable for human consumption or food production is produced on demand by the addition of denaturants such as eosin, patent blue, or soda ash.

Treated salt is used in water softening, textile treatment, the leather industry, animal feed production, and in many other fields.

Of the above, the regeneration of water-softening ion exchangers is a very important application [60]. Water softening is essential owing to the widespread occurrence of hard water, and so far there is no alternative to the long-established and well-proven method based on ion exchangers and salt.

6.1.3. *Industrial salt*

Industrial salt is salt that is used as raw material for producing other compounds [61], [62]. The main applications of industrial salt in the chemical industry are in chlor-alkali electrolysis (⟶ Chlorine, ⟶ Sodium Hydroxide) and sodium carbonate (⟶ Sodium Carbonates) production.

The products obtained form the basic raw materials for innumerable other products, including glass, dyes, washing and cleaning agents, medicines, plastics, aluminum, and paper (Fig. 14).

Figure 14. Family tree of salt chemistry [63]

In Germany in 2003, about 6.2×10^6 t rock salt was used, and about 6.7×10^6 t in the form of brine.

As with all forms of salt, industrial salt is subject to tax laws, but it may be used without being denatured if a salt license has been issued. For technical reasons, no anticaking agents are added to industrial salt.

6.1.4. *De-icing Salt*

Rock salt and sea salt can be used for de-icing road surfaces to give safe driving conditions for traffic in winter. The chemical processes (hydration) that take place when de-icing salt comes into contact with snow and ice on the roads in winter effectively eliminate slippery conditions [64], [95].

The effect of de-icing salt on the environment has been the subject of controversy. However, in the wake of mounting evidence from scientifically based investigations, there is now little opposition to the sparing application of de-icing salt to ensure the safety of traffic, and the frequency of accidents caused by snow and ice can be drastically reduced.

The development and use of suitable technology have contributed greatly to decreasing the amount of de-icing salt used and hence to reduction of environmental pollution. This technology makes use of modern electronic equipment for automatically adjusting the salt spreading process to the width of the road and the speed of the gritting vehicles, and the spreading of moist salt.

For the spreading of moist salt, the dry salt is wetted with a 5 – 30 % solution of sodium chloride, calcium chloride, or magnesium chloride. Moistening prevents windblown losses and gives a more rapid de-icing effect [64]. For this purpose, the distillation wastewater of the Solvay Process (⟶ Sodium Carbonates – Ammonia – Soda Process) can be used as well, because it contains about 115 kg calcium chloride and about 50 kg sodium chloride per cubic meter of solution.

In practise, the ratio between de-icing salt and solution is usually 70/30. In this case, dry salt is stored in the salt-dispensing vehicle and moistened with the solution instantaneously when dispersed. Another method is to store a moist mixture of 95 % salt and 5 % solution in a tank in the vehicle and spread this mixture.

In the 1960s, at least 40 g/m^2 de-icing salt was required, but subsequent technical developments have enabled an optimum de-icing effect to be achieved with only 10 – 20 g/m^2. In 2003, ca. 1.7×10^6 t of de-icing salt was produced in Germany.

6.2. Packaging, Transport, and Storage

Salt is supplied both loose and in packaged form. Salt for human consumption is available in big bags, in plastic and paper sacks, and in small packets. Denatured salt and de-icing salt are supplied loose or in packages, but salt intended for large-scale industrial use is only supplied in loose form.

Salt is transported by canal and river boats, or by road in tipping trucks, flat trucks, or silo trucks.

6.3. Economic Data

The world reserves of salt are very large. Economic and subeconomic deposits of salt are substantial in principal salt producing countries. The oceans contain an estimated amount of 5×10^{16} t of mineral salts [96], which is a practically inexhaustible supply of salt. The world production of salt exceeded 200×10^{6} t in 1996 for the first time [72].

A list of the most important salt producers in Germany follows:

esco – european salt company GmbH & Co. KG, Hannover (Bergwerk Bernburg; Saline Bernburg; Bergwerk Borth; Saline Borth; Bergwerk Braunschweig-Lüneburg; Bergwerk Hattorf)
Saline Luisenhall GmbH, Göttigen (Saline Luisenhall)
Südsalz GmbH, München (Bergwerk Berchtesgaden; Saline Bad Reichenhall; Saline Bad Friedrichshall)
Südwestdeutsche Salzwerke AG, Heilbronn (Bergwerk Heilbronn)
Wacker-Chemie GmbH, München (Bergwerk Stetten)

Figure 15 shows production and consumption figures in Germany for the years 2002 and 2003, respectively, classified according to use.

Figure 15. Domestic salt production and sales in Germany in 2002 and 2003, respectively [97]

Figure 16 shows the statistical development of salt works and salt mines in Germany.

Figure 16. Statistical development of salt works and salt mines in Germany [97]

4. Uses 3
5. References 3

1. Introduction

The discovery of the sandwich structure of ferrocene [bis(cyclopentadienyl)iron] in 1952 provided the impetus for fundamental changes in research in the field of organometallic compounds. One method of preparing ferrocene is by reaction of cyclopentadienylsodium with an iron halide or complex halide in a polar solvent such as THF [1].

2. Structure and Properties

The properties, reactions, and preparation of organosodium and –potassium compounds are described in detail in [2].

The organosodium and organopotassium compounds are generally ionic, in contrast to the corresponding lithium compounds. The ionic character of the metal – carbon bond increases with increasing electropositivity and atomic radius of the metal [3]. The chemical reactivity of the ionic organometallic compounds depends mainly on the carbanion. The carbanions can be divided into the following categories [4]:

1) Carbanions with localized charge: the negative charge is restricted to a single carbon atom (e.g., H_3C^-)
2) Carbanions with delocalized charge: the negative charge is distributed over two or more carbon atoms (e.g., $(C_6H_5)_3C^-$)
3) Radical carbanions: these are aromatic molecules that have acquired one (sometimes two) electrons (e.g., $C_{10}H_8^{\cdot -}$)

1) Organosodium and organopotassium compounds that contain carbanions with localized charge are extremely reactive and exhibit salt-like properties such as high melting point, low vapor pressure, and very low solubility in nonpolar solvents such as pentane or hexane [5]. Methylpotassium, for example, has a crystalline structure of the nickel arsenide type [4], with a trigonal prismatic arrangement of six potassium ions around a central methyl carbanion [3], [6]. The thermal stability of the sodium and potassium compounds is in general lower than that of the corresponding lithium compound, the potassium compounds often being unstable at room temperature. They generally ignite spontaneously on exposure to air and react violently with water.
2) Typical properties of organosodium and -potassium compounds of carbanions with delocalized negative charge include intense color, solubility in ether, and higher stability than that of the simple alkyl compounds, although they are also air and moisture sensitive. These properties are a result of the delocalization of the negative charge over the entire organic ligand [3]. Carbanions can be planar (sp^2 hybridization) or pyramidal (sp^3 hybridization). All the intermediate configurations are also possible, depending on the nature of the substituents. If one or more groups bonded to the carbanion stabilize the ion by conjugation, the sp^2 configuration is favored, since a planar arrangement ensures maximum overlap of the *p*-orbitals. This is true of the bonds of the central carbon atom in the triphenylmethyl carbanion [7]:

If triphenylmethyl chloride is reacted with sodium in an inert solvent, the chlorine

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_341

atom is displaced by sodium, and the deep red, ether-soluble compound tritylsodium is formed:

$$(C_6H_5)_3CCl \xrightarrow{Na/Hg} (C_6H_5)_3CNa$$

The solution of triphenylmethylsodium is used as an extremely strong base, the carbanion being a very good proton acceptor [7].

The cyclopentadienyl anion [7] produced when a hydrogen atom is cleaved from cyclopentadiene is stabilized by delocalization of the six π-electrons over all five carbon atoms to give a quasi-aromatic structure.

$C_5H_6 + Na \longrightarrow C_5H_5Na + 1/2\,H_2$

Another example is fluorenylpotassium [3]:

Owing to the charge delocalization, the effective radius of the anion is large, so that the coulombic interaction between cation and anion is weak. Therefore, salts of these anions are weakly dissociated in polar aprotic solvents such as hexamethylphosphoramide $[(CH_3)_2N]_3PO$ [8].

3) Direct transfer of an electron from the metal atom to the organic ligand results in formation of a radical anion [4]:

$C_{10}H_8 + K \longrightarrow K^+\,C_{10}H_8^{\cdot\,-}$

Radical ions are only stable at low temperature [9]. They decompose on heating to room temperature, whereby metalation of the organic group with loss of hydrogen can take place.

Sodium naphthalide and related compounds are strong reducing agents. As they are very soluble in ethers, they are often used in preference to sodium, which is insoluble. The resulting homogeneous reaction is usually faster, and is easier to control than a heterogeneous reaction between dissolved components and solid sodium [8].

3. Preparation

Under normal conditions, organosodium and organopotassium compounds cannot be obtained from alkyl halides and sodium or potassium metal [10]. With these metals, the main products are alkanes (Wurtz reaction) [5]. In hydrocarbon solvents alkyl halides react with sodium to give sodium alkyls as intermediates, which react with further alkyl halide to give the alkane [7]. In the case of alkyl chlorides, special methods are available to largely suppress the condensation reaction and direct the reaction towards the formation of organosodium compounds [3]. Halogenated alkanes can react explosively with highly reactive metals such as sodium or potassium. The commonly used method of removing traces of moisture from solvents by treatment with sodium must therefore never be used with halogenated alkanes [11].

Organosodium and -potassium compounds are accessible by three types of reaction:

Metalation. [3] Acidic hydrogen atoms can be replaced by sodium or potassium. The reaction can be carried out using the metal itself or a metal hydride, amide, alkoxide, or alkyl.

$$Ph{-}C{\equiv}CH + Na \longrightarrow Ph{-}C{\equiv}CNa + 1/2\,H_2$$

$$Ph_2CH_2 + NaNH_2 \longrightarrow Ph_2CHNa + NH_3$$

Halogen atoms can also be substituted:

$$CH_2{=}CHCl + 2\,Na \longrightarrow CH_2{=}CHNa + NaCl$$

The planar aromatic cyclopentadienyl ion $C_5H_5^-$ can be obtained by reductive cleavage of the C–H bond in cyclopentadiene, for which either metallic Na or NaH can be used [8]:

$$C_5H_6 + Na \xrightarrow{THF} Na[C_5H_5] + 1/2\,H_2$$

Transmetalation. [3] The transfer of an organic radical from one metal atom to another (e.g., sodium or potassium) is another method of producing organosodium or organopotassium compounds:

$$Me_2Hg + 2\,Na \longrightarrow 2\,NaMe + Hg$$

$$(CH_3CH_2)_2Hg + 2\,Na \longrightarrow 2\,CH_3CH_2Na + Hg$$

Electron Transfer. [3] The first product of the addition of sodium or potassium to an unsaturated organic system is a radical ion, which can react with a further metal atom to give a dianion. Radical anions are usually prepared by reacting a suitable hydrocarbon (e.g., anthracene) with sodium or potassium (e.g., in the form of an amalgam) at low temperature:

$$C_{14}H_{10} + Na/Hg \xrightarrow[-80\,^{\circ}C]{\text{Solvent}} Na^{+}\,C_{14}H_{10}^{\bullet -}$$

4. Uses

The organosodium compounds are of little industrial importance, apart from some that are used as catalysts. The so-called alfin catalysts for the copolymerization of butadiene with styrene or isoprene consist of allylsodium, iso-C_3H_7ONa, and NaCl.

Alkali-metal organometallics occur as intermediates in the reaction of halobenzenes with alkyl halides in the presence of sodium in ether solution, for the production of alkylbenzenes. The Wurtz–Fittig reaction takes place in two stages [10].

The yield of alkylbenzene depends mainly on whether the aromatic-bound halogen is more rapidly replaced by sodium than the aliphatic-bound halogen.

Further, phenylsodium must react more rapidly with the alkyl halide than with the aryl halide, i. e., the carbon–halogen bond in the alkyl halide must be more readily polarizable than that in the aryl halide.

Triphenylphosphine and tetraethyllead can be prepared by using modified Wurtz–Fittig reactions.

$$3\,C_6H_5Cl + PCl_3 + 6\,Na \longrightarrow (C_6H_5)_3P + 6\,NaCl$$

$$4\,PbNa + 4\,ClC_2H_5 \longrightarrow Pb\,(C_2H_5)_4 + 4\,NaCl + 3\,Pb$$

Sodium naphthalide, $Na^{+}\,[C_{10}H_8]^{-}$, in ether is often used as a strong reducing agent. The blue solution of sodium and benzophenone in THF is an effective reagent for removing traces of oxygen from nitrogen [12].

Cyclopentadienylsodium readily takes part in a metathetical reaction with many halides of *p*-block elements, forming σ- or π-bonded cyclopentadienyl compounds. Cyclopentadienylsodium reacts with transition metal halides to form metallocenes, for example:

$$2\,Na[C_5H_5] + MnCl_2 \xrightarrow{THF} Mn[C_5H_5]_2 + 2\,NaCl$$

The bis-cyclopentadienyl complexes of Fe, Co, and Ni can also be readily prepared by this method [8].

Organosodium and organopotassium compounds initiate the anionic polymerization of alkenes. Alkenes undergo insertion into the metal–carbon σ-bond, forming a new organopotassium compound with a longer chain [3]:

Owing to their great reactivity and capacity for spontaneous ignition in air, these compounds are used in situ as intermediate products and are seldom isolated.

1. Introduction

Pure sodium hydroxide, NaOH, is a colorless solid. It does not occur in nature, but is manufactured on a large scale from fairly readily obtainable raw materials and is used in numerous chemical processes. Because of its corrosive action on many substances, it is known as caustic soda.

Sodium hydroxide solution is one of the oldest man-made chemicals. The reaction of sodium carbonate with calcined limestone (causticization of soda) was already known in early Afro-Oriental cultures. Alabaster vessels containing 3 % sodium hydroxide solution have been found in Egyptian tombs dating from 3rd century B.C. near the Pyramid of Cheops. The first written records of caustic soda production during the early years A.D. came from Egypt and India.

2. Properties

Because pure sodium hydroxide has a high affinity for water, the physical and chemical properties of the pure substance are difficult to determine. Many of the data are obtainable only by extrapolating values for impure sodium hydroxide. The same is true for the concentration-dependent physical properties of aqueous solutions of sodium hydroxide, since these solutions have a strong tendency toward supersaturation.

2.1. Properties of Sodium Hydroxide

Some physical properties of solid sodium hydroxide are as follows:

M_r	40
Appearance	white, crystalline
Density (liquid, 350 °C)	1.77 g/cm^3
mp (soda and water free)	322 ± 2 °C
Heat of fusion	6.77 kJ/mol
Boiling point at 0.1 MPa	1388 °C (calculated)
Specific heat capacity at 20 °C	3.24 J kg^{-1} K^{-1}

Chemical Properties. Pure sodium hydroxide is strongly hygroscopic. It dissolves in water with liberation of heat and forms six defined hydrates (see Figs. 1 and 2, and Table 1). When transporting and storing sodium hydroxide solution, the containers must be heated or insulated because the melting points of some of the hydrates are much greater than 0 °C. In the presence of moisture, NaOH reacts readily with atmospheric carbon dioxide to form sodium carbonate. Sodium hydroxide reacts with carbon monoxide under pressure and in the presence of moisture to yield sodium formate.

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_345.pub2

The high affinity of sodium hydroxide for water causes a reduction in water vapor pressure (e.g., to 0.36 kPa for 50.3 wt % NaOH at 30 °C). Sodium hydroxide is therefore a very effective drying agent. It is fairly readily soluble in methanol and ethanol.

Table 1. Stability of the hydrates of sodium hydroxide

Formula	Stability range, °C
$NaOH \cdot 7H_2O$	− 23.5 to − 28.3 [a]
$NaOH \cdot 5H_2O$	− 12.2 to − 31.9 [a]
α-$NaOH \cdot 4H_2O$	+ 7.6 to − 21.4 [a]
β-$NaOH \cdot 4H_2O$ (unstable)	− 1.7 to − 14.5 [a]
$NaOH \cdot 3.5H_2O$	+ 15.6 to − 8.8 [b]
$9NaOH \cdot 28H_2O$ (unstable)	+ 2.7 to − 2.5 [a]
$NaOH \cdot 2H_2O$	0 to + 12.5 [c]
$NaOH \cdot H_2O$	+ 4.5 to + 64.3 [b]

[a] Unstable melting point.
[b] Clearly defined melting point.
[c] Melting point can be determined only by extrapolation.

Figure 1. The NaOH – H_2O system

Anhydrous sodium hydroxide reacts very slowly with most substances. For example, it attacks many metals only slightly at room temperature (e.g., Fe, Mg, Ca, and Cd). However, corrosion rates increase rapidly with increasing temperature. More noble metals such as nickel, silver, gold, and platinum are attacked only slightly even when heated, especially if oxidizing atmospheres are excluded. Anhydrous sodium hydroxide does not react with dry carbon dioxide.

2.2. Properties of Sodium Hydroxide Solution

Physical Properties. The concentrations of the aqueous solutions in equilibrium with solid NaOH at various temperatures are given below:

Figure 2. Melting diagram of the NaOH–H_2O system [1]

t, °C	10	18	30	40	53	64
wt % NaOH	49.8	51.0	53.3	55.4	59.7	69.0

The heat of solution is ca. 44 kJ/mol at 18 °C. The surface tension at 20 °C increases from 7.46×10^{-2} N/m for a 5 wt % solution to 0.1 N/m for a 35 wt % solution [2]. A 1 mol % solution has a surface tension of 7.43×10^{-2} N/m at 20 °C, which decreases to 6.23×10^{-2} N/m at 90 °C.

The density of aqueous sodium hydroxide solution in the concentration range 0 – 20 wt % can be calculated from the formula:

$$d_1 = d_2 + (1.16027 \times 10^{-2} - 2.511 \times 10^{-5} t + 1.0222 \times 10^{-7} t^2) p - (1.0817 \times 10^{-5} - 3.6748 \times 10^{-7} t + 2.034 \times 10^{-10} t^2) p^2$$

where

d_1, g/cm^3 = density of solution at t °C
t, °C = temperature

p, wt % = g NaOH/100 g solution
d_2, g/cm^3 = density of water at t °C

The densities of more concentrated aqueous sodium hydroxide solutions at 20 °C are as follows:

[NaOH], wt %	Density, g/cm^3
20	1.219
30	1.328
40	1.430
50	1.525

The boiling point curve is shown in Figure 1. In the concentration range 0 – 60 wt % NaOH, the boiling point increases approximately linearly with temperature.

NaOH concentration, wt %	5.9	23.1	33.8	48.3	54.6
Boiling point, °C	105	110	120	140	150

A 5 g/L solution of sodium hydroxide in water is almost completely dissociated. Activity coefficients are in the range $a = 0.784$ (0.1 M at 10 °C) and $a = 3.922$ (15 M at 70 °C).

Chemical Properties. Amphoteric metals such as zinc, aluminum, tin, and lead are attacked by dilute sodium hydroxide solution at room temperature. Iron, stainless steel, and nickel are fairly resistant.

3. Production

Sodium hydroxide is produced commercially in two forms: as 50 wt % solution (the most common form) and in the solid state (caustic soda) as prills, flakes, or cast shapes.

3.1. Production of Sodium Hydroxide Solution

Electrolysis of Sodium Chloride. Sodium hydroxide solution is produced industrially mainly by the electrolysis of sodium chloride. This yields sodium hydroxide solution, chlorine, and hydrogen in the mass ratio 1: 0.88: 0.025 in accordance with the following overall equation:

$$2\,NaCl + 2\,H_2O \rightarrow 2\,NaOH + Cl_2 + H_2$$

In the early 1980s, the membrane process was introduced, the other processes in operation at that time being the amalgam and diaphragm processes. Chlor-alkali production in 2004 was divided between the different processes as shown in Table 2.

Membrane technology continued to gain market share in 2004. Based on announced capacity changes, membrane processes will account for about 44 % of the total installed chlor-alkali capacity by 2009. Membrane technology saves approximately 30 % electrical power and is the best available technique, so it will be increasingly used in new units.

In Japan, by 1988 all plants based on the amalgam process had been either shut down or converted to the membrane process. Some Japanese diaphragm plants were also replaced by membrane plants for reasons of both cost and quality. Details of the three electrolytic processes are given in → Chlorine.

Treatment of the liquor from the electrolytic cell is shown schematically in Figure 3. In the amalgam process, sodium hydroxide solution is produced from sodium amalgam and water over a graphite catalyst at 80 – 120 °C. The 50 wt % solution produced is very pure. It is cooled, mercury is removed by centrifugation or filtration through cartridge or pressure plate filters, and it is then sold without further treatment.

In the diaphragm cell, the depleted sodium chloride solution from the anode compartment is transferred quantitatively to the cathode compartment, so that the cell liquor produced there contains ca. 18 wt % sodium chloride and 10 – 15 wt % sodium hydroxide. During evaporation to give a 50 wt % NaOH solution, all the impurities carried over with the depleted sodium chloride solution are removed to their limiting solubility by fractional crystallization; thus the sodium chloride content can only be reduced to ca. 1 – 1.5 wt %. In the DH process of the PPG Company, further purification is carried out by extraction with anhydrous liquid ammonia. This gives a product comparable to that from the amalgam process (rayon quality), but the process is seldom used because of cost. This is also true of a Japanese process in which a relatively pure sodium hydroxide solution is obtained by cooling the 50 wt % diaphragm liquor and recovering the crystals of pure $NaOH \cdot 3.5\,H_2O$ formed. Details of the evaporation and purification processes are given in → Chlorine. Methods of optimizing the various evaporation systems

Table 2. Distribution of chlor-alkali production among the three most widely used processes (percentage of installed capacity in 2004)

Process	North America	Western Europe	Japan
Amalgam	19	44	0
Diaphragm	39	7	3
Membrane	25	34	82
Others	17	15	15

Figure 3. Treatment of the sodium hydroxide solution from electrolysis cells

Figure 4. Membrane cell caustic evaporation (Bertrams process)

used for treating liquor from the diaphragm cell are described in [3].

In the membrane process, a hydraulically impermeable membrane prevents mixing of the electrolytes. This process produces a high-purity, virtually chloride-free sodium hydroxide solution comparable to that of the amalgam process. However, the chloride content increases by a factor of ca. 10 if operation of the cell is interrupted, due to diffusion of Cl^- ions through the membrane. The sulfate and chlorate present in the anolyte also affect the concentration of these impurities in the caustic liquor from the membrane cell, since the cation-selective membrane has an appreciable residual permeability for anions. Most membrane cells give optimum economic performance at a NaOH concentration of 30 – 35 wt %. An ion-exchange membrane has now been developed that enables a 50 wt % sodium hydroxide solution to be produced in the cell [4], although a considerable increase in voltage is required. Such membranes are viable only if steam costs are high and electricity costs low [5]. The 30 – 33 wt % sodium hydroxide solution is usually concentrated in a two- or three-stage falling-film evaporator (depending on steam costs and plant size) to give a commercial 50 wt % solution (see Fig. 4). For a three-stage evaporator, the steam consumption is 0.55 t per ton NaOH (100 %), and for a two-stage evaporator, 0.71 t per ton NaOH (100 %), with sodium hydroxide solution and steam in counter current flow.

The evaporation of membrane cell liquor (unlike that of diaphragm cell liquor) does not produce any solid material that can foul the heat exchanger or erode the pipework. The pickup of metals during evaporation is ca.1 wt ppm if appropriate construction materials are used (nickel, stainless steel). The various evaporation techniques are described in [3], with special reference to the concentration of membrane cell liquor.

As shown in Table 3, the three electrolytic processes have different energy requirements. The membrane process consumes the least electrical energy (2200 – 2500 kW · h per ton NaOH) but requires an additional 200–300 kW · h per ton NaOH in the form of steam to produce a 50 wt % solution. The diaphragm process consumes less electrical energy than the amalgam process but requires 700–900 kW · h per ton NaOH as steam for the evaporation stage and therefore has the highest total energy requirement.

Because of the high consumption of electrical energy, much research has been aimed at reducing the cell voltage. A ca. 1 V reduction can be achieved by using an oxygen diffusion cathode (as in a fuel cell) in the membrane cell process, although in this case no byproduct hydrogen is produced. This technology is gaining increasing interest. Cell design, oxygen diffusion cathode, and integration of the cathode into the cell design are priority points of development. Also the investigation of operation parameters and the periphery of the cells are in focus. Currently (in 2005) these cells have not been used on a production scale [7 – 9].

The electrolysis of fused NaCl at 350 °C with a β-Al_2O_3 diaphragm is also of interest. In laboratory-scale cells, a power consumption of 2350 kW · h per ton NaOH can be attained [10]. This technique, too, has yet to be used on a commercial scale.

Other Processes. The causticization of sodium carbonate solution is the oldest method of producing sodium hydroxide and was the only method available until the introduction of electrolysis. Although it had almost disappeared from use, it is now of special interest for companies with access to synthetic sodium carbonate from the Solvay process or to natural sodium carbonate (e.g., trona, $Na_3H(CO_3)_2 \cdot 2\,H_2O$). In this process, a hot, ca. 12 % solution of sodium carbonate is mixed with quicklime. The calcium carbonate that precipitates according to the equation.

$$Na_2CO_3 + CaO + H_2O \rightarrow 2\,NaOH + CaCO_3$$

is removed, and the ca. 12 % solution of sodium hydroxide is evaporated in several stages. The impurities that precipitate, mainly NaCl and Na_2SO_4, are filtered off. Further details on the causticization of sodium carbonate are given in [11].

In a combination of electrolytic and dialysis cells, sodium salts can be split into the corresponding acids and alkalis, e.g.,

$$Na_2SO_4 + 2\,H_2O \rightarrow 2\,NaOH + H_2SO_4$$

This reaction can be carried out in a two-chamber cell with a cation- or anion-exchange

Table 3. Energy requirements for the production of 1 t of sodium hydroxide (as 50 wt % solution) by the three electrolytic processes

Energy, kW · h/t NaOH [a]	Process		
	Amalgam	Diaphragm	Membrane
Electricity [b]	2800 – 3200	2500 – 2600	2200 – 2500
Steam (equivalent) [c]	0	700 – 900	90 – 180
Total	2800 – 3200	3200 – 3500	2290 – 2680
Relative energy costs, %	90	100	70

[a] The energy requirement given is based on the production of 1 t NaOH, 0.88 t Cl_2, and 0.025 t H_2.
[b] In dependence on the current density.
[c] 1 t steam is taken to be equivalent to 400 kWh of electrical energy.

membrane; in a three-chamber cell with a cation-exchange and an anion-exchange membrane; or in a multichamber cell with a combination of cation, anion, and bipolar membranes [12 – 15] (→ Sodium Sulfates, Chap. 1.4.1). However, in all industrially operated cells, the product is a dilute sodium hydroxide solution (15 – 30 wt %), which also contains some of the salt used as starting material. For this reason, this type of process is most suitable for treating sodium-salt containing wastewater from processes in which the dilute sodium hydroxide solution obtained can be recycled for neutralization purposes.

An alternative method of producing sodium hydroxide solution for small paper pulp plants, the ferrite recovery process, is described in [16]. Here, waste liquor containing sodium salts and organic substances is evaporated, and the residue is mixed with Fe_2O_3 and calcined. The sodium ferrite formed is decomposed by water to give NaOH and Fe_2O_3.

3.2. Production of Solid Sodium Hydroxide

Solid sodium hydroxide (caustic soda) is obtained by evaporating sodium hydroxide solution until the water content is $< 0.5 – 1.5$ wt %. The most efficient utilization of energy is achieved with multistage equipment. A flow diagram of a plant constructed by Bertrams, Basel (Switzerland), is shown in Figure 5.

A 50 wt % solution is vacuum evaporated in a preconcentration unit, by using the heat of the vapor from the main concentrator, until the concentration reaches ca. 60 wt %. In the second stage, a concentration of ca. 99 wt % is attained by heating with a molten salt heat-transfer medium ($NaNO_2 – NaNO_3 – KNO_3$) at $>$ 400 °C in a falling-film evaporator. The product is fed to a flash evaporator that operates as a gaslift pump. Molten NaOH is raised by vacuum into a heated riser pipe, causing the remaining water to evaporate. The rising steam bubbles lift the melt to the highest point of the system, where the steam is pumped off. The almost anhydrous melt passes through a downcomer pipe into the holding vessel, from which it is pumped to the conditioning plant. The holding vessel, pumps, and pipes must be heated to prevent premature crystallization.

3.3. Forming

When the NaOH melt is cooled and formed, both the solidification point of NaOH (322 °C) and that of the monohydrate, NaOH · H_2O (62 °C), must be passed through quickly to prevent caking due to unsolidified monohydrate.

Solid sodium hydroxide is supplied in the form of flakes, prills, cast blocks, and less commonly as tablets, briquettes, or granules. Flakes have a bulk density of ca. 0.9 kg/dm^3, a thickness of ca. 1.5 mm, and a diameter of 5 – 20 mm, and are easily broken so that some dust is always formed on handling. Prills have a bulk density of $>$ 1 kg/dm^3 and consist of spheres with a diameter of 0.1 – 0.8 mm (microprills) or 0.5 – 2.5 mm.

Flakes. To produce flakes, molten NaOH is fed into a trough in which an internally cooled drum rotates. The molten material solidifies on the surface of the partially immersed drum and is scraped off by a knife, which breaks up the sheet of NaOH into flakes. These are taken to a small intermediate storage silo and packed as soon as possible in sacks or steel drums. The material

Figure 5. High-Concentration unit for caustic soda (Bertrams process)

tends to bridge due to its particle shape, so that it cannot be stored in large silos or be transported by compressed air.

Figure 6. Production of sodium hydroxide prills (Bertrams process)
a) Caustic melt tank; b) Caustic melt pump; c) Spray tower; d) Rotating spray system; e) Product cooler; f) Elevator; g) Exhaust air treatment; h) Silo; i) Bagging and pelletizing

Prills are produced by spraying the molten material at ca. 360 °C to form droplets. The spray equipment used can be nozzles (outdated), or a spinning disk or basket. The finely divided melt forms spheres of fairly uniform diameter due to surface tension. These are cooled to ca. 250 °C as they fall down a shaft in which air flows upward. The prills are collected in a funnel from which they run into a cooling drum where they are cooled to ca. 50 °C. The finished product is stored in silos (see Fig. 6).

Unlike flakes, prills are free flowing. Also, they do not cake as readily and thus can be stored in silos, transported in containers or other large vessels, or moved by compressed air, because they are almost dust free.

Cast Blocks. Molten NaOH is directly cast into iron drums or similar containers. The drums are externally cooled intensively by spraying with water, so that a solid film of sodium hydroxide forms immediately on the walls of the container, preventing further contamination by the iron.

Special Shapes. Tablets, pills, or pellets are produced by the droplet process. Molten NaOH drops from a special device made of silver onto a slowly rotating cooled table or conveyor belt (pill machine). The product has a very low content of metallic impurities, so that this process is especially suitable for producing small quantities (e.g., for analytical purposes).

3.4. Specifications

A review of the grades of 50 wt % sodium hydroxide solution produced by the various processes is given in → Chlorine. Diaphragm liquor cannot be used in all applications (e.g., for viscose manufacture or various organic processes) because of the amounts of chloride, chlorate, and heavy metals present.

When corrosion-resistant materials are used for sodium hydroxide production (nickel and stainless steel), the pickup of metal (Ni, Fe) is < 1 ppm. Solid caustic soda should have a pure white appearance. The most important impurities in solid sodium hydroxide are listed in Table 4.

3.5. Storage, Packaging, and Transportation

Iron, stainless steel, and nickel are suitable materials for containers used for transport and storage, as well as for pipelines. However, corrosion resistance is not the sole criterion for the choice of material. Stress corrosion cracking, changes in the crystal structure, and pitting can cause sudden material failure, so that a more expensive material is often chosen for safety reasons.

Vessels for holding aqueous solutions of sodium hydroxide are usually constructed of alkali-resistant steel. However, at > 50 °C or in the presence of oxygen, iron is slowly attacked by sodium hydroxide solution. For a high-quality product (e.g., with iron content $<$ 1 mg/kg), cladding (rubber or plastic coating) is required. At < 50 °C the solution can be transported by pipes of alkali-resistant steel or plastic (e.g., PVC). Iron pipes are always kept full to prevent corrosion due to ingress of air and consequent black coloration of the solution. At higher temperature, coated materials such as rubber-lined steel, austenitic Cr – Ni steel (e.g., DIN 1.4541), nickel, Hypalon, epoxy resin, polypropylene, or glass fiber reinforced composites are suitable. In the latter case, an inner lining must be used to prevent contact between the glass fiber and the solution. Heat exchangers are usually constructed of nickel, nickel alloys, or stainless steel because of the high temperature. For equipment handling highly concentrated solutions, nickel is the most commonly used material because of its outstanding corrosion resistance. Metals that have been in contact with solutions are difficult to weld, so that repairs to pipework and equipment which have carried sodium hydroxide solutions are difficult. A comprehensive review of materials that can be used with sodium hydroxide is given in [17].

Pipelines carrying 50 wt % sodium hydroxide solution in cold regions are provided with thermostatic heating. Solutions are transported by road, rail tanker, or ship.

Caustic soda prills are stored in steel or stainless steel hoppers with a capacity of 30 – 50 m^3. The hoppers have conical bases with an angle of 25° to the vertical and are provided with external hammering equipment. Even when the product is stored under dry air, a storage time of 3 – 6 d should not be exceeded to ensure that the prills do not cake under their own weight. Solid sodium hydroxide is usually packed in 25 – 50-kg hermetically sealed polyethylene sacks. For transport, the sacks are stacked on wooden palettes and shrink wrapped in polyethylene. Caustic soda prills are also carried in 50- or 200-kg steel drums, loose in 1000-kg-capacity steel or flexible containers, or in transportable hoppers. In the closed system delivery (CSD) method of the PPG Company, containers coated with epoxy resin are transported by road and rail. Pneumatic transport is carried out with dry air and causes very little damage to the product [18].

4. Uses

Most users of sodium hydroxide require dilute aqueous solutions.

The sodium hydroxide produced in Europe (9.86×10^6 t/a NaOH) and in North America in 2004 was divided among various areas of use,

Table 4. Product quality: typical percentage analyses of sodium hydroxide from chlor-alkali electrolytic processes

	Amalgam process	Membrane process	Diaphragm process
NaOH	99 – 99.5	99 – 99.5	98 – 99
NaCl	0.03 – 0.05	0.01 – 0.02	1 – 2
Na_2CO_3	0.2 – 0.4	0.2 – 0.4	0.65
Na_2SO_4	0.03	0.001 – 0.01	0.035
Ca	0.002	0.00002	0.001
Mg	0.0005	0.00002	0.0004
Fe	0.001	0.0001 – 0.001	0.0006 – 0.0015
Al	0.001	0.00002	0.0005
Ni	0.0002 – 0.0004	0.0002 – 0.0004	0.0002 – 0.0004
Hg	0.000001 – 0.00001	Hg free	Hg free
mp, °C	322	322	322

Figure 7. Demand of sodium hydroxide in Europe in 2004 broken down by major end uses (Source Bayer MaterialScience AG)

as shown in Figure 7 and 8. More than 56 % of production is used in the chemical industry:

1) In inorganic chemistry, sodium hydroxide is used in the manufacture of sodium salts, for alkaline ore digestion, and for pH regulation.
2) The organic chemical industry uses sodium hydroxide for saponification reactions, production of nucleophilic anionic intermediates, etherification and esterification, basic catalysis, and the production of free organic bases. Sodium hydroxide solution is used for scrubbing waste gases and neutralizing wastewater.
3) In the paper industry (→ Paper and Pulp, Chap. 1.3.1,→ Paper and Pulp, Chap. 1.3.2), sodium hydroxide solution is used for cooking wood (removal of lignin).
4) The textile industry uses sodium hydroxide solution to manufacture viscose and viscose staple fibers (→ Cellulose, Chap. 3.1). The sodium hydroxide solution used must contain only traces of chloride ions (rayon quality). The surface of cotton can be improved by treatment with sodium hydroxide solution (mercerization).
5) Considerable quantities of sodium hydroxide are used for sodium phosphate production in the detergent industry. Soaps are manufactured by the saponification of fats and oils with sodium hydroxide solution, and detergents are produced from organic sulfonic acids and sodium hydroxide.
6) In the aluminum industry, sodium hydroxide is used mainly for the treatment of bauxite.

Figure 8. Demand of sodium hydroxide in North America in 2004 broken down by major end uses (Source Bayer MaterialScience AG)

Figure 9. World production capacity of sodium hydroxide by region (total: 59 557 000 t in 2004) (Source Bayer MaterialScience AG)

Figure 10. U.S. production of chlorine and sodium hydroxide solution (Source Bayer MaterialScience AG)

7) Waterworks use dilute sodium hydroxide solution to regenerate ion exchangers for water purification and wastewater treatment.
8) Other users of sodium hydroxide include electroplating technology, the natural gas and petroleum industries, the glass and steel industries, and gold extraction (cyanide leaching). In the food industry, sodium hydroxide is used for degreasing, cleaning, and for peeling potatoes.

Consumption of caustic soda in pulp and paper accounts for about one quarter of global caustic demand. The pulp and paper markets are relatively mature markets, so demand growth will be rather slow. The remaining 75 % of global NaOH demand is inclined to follow the health of the local manufacturing base, which is tied to the local gross domestic product (GDP).

5. Safety Precautions

Because of its strongly caustic action, all contact with sodium hydroxide during handling must be prevented by the use of suitable protective equipment (protective goggles, safety gloves, and, if needed, dust masks). Any clothing or shoes that come in contact with sodium hydroxide must be removed immediately and can be reused only after thorough cleaning. First aid to affected parts of the body consists of washing with copious amounts of water. The skin can be neutralized with a dilute solution of a buffered weak acid (e.g., acetic acid – sodium acetate). For irrigation of the eyes, a special hygienic eyewash solution is used. The product poses no direct environmental risk and has therefore been removed from the list of chemicals (e.g., in the United States) whose emission must be reported to local and national environmental authorities.

6. Economic Aspects

Chlor – alkali plants are operated to meet chlorine demand; therefore outputs are typically connected to chlorine production. Chlor – alkali operating rates will be on a steady climb, as global economics growth is stable.

Global chlorine demand is primarily driven by production of commodities such as PVC, used, for example in construction parts, and isocyanates, going into construction parts, furniture, shoe industry, consumer durables, and automobiles. These markets follow the local GDP trend, thus more mature economies will typically have a lower GDP and a lower growth in chlorine demand for these end uses.

The world production capacity of sodium hydroxide in 2004 is estimated to be approx. 60×10^6 dry metric tons (dmt) per year. Today 41 % of sodium hydroxide is produced in Asia (Fig. 9). In contrast the chlor – alkali production in the US has shown a decreasing tendency in recent years due to increasing energy costs and a smaller share in production of vinyl compounds (Fig. 10). Even though the same trend holds true for Western Europe, the production remains on a constant level. From 2004 to 2009 the global

Figure 11. Sodium hydroxide production in Germany and the United States, 1999 – 2005 (Source Bayer MaterialScience AG)

market for caustic soda will increase by 2.8 % on average (demand in 2004 is estimated to be approx. 51×10^6 t, 100 %). Growing markets are textiles, water treatment, alumina production, and pulp and paper.

In order to show the different growth rates in the USA and Germany, the development of the US market is shown in Figure 10. and a comparison of the two markets in Figure 11.

1. Sodium Sulfate

1.1. History and Natural Occurrence

Sodium sulfate has been known since the 1500 s. Its use in the form of spa water or as a salt goes back even further. It was first described in 1658 by J. R. GLAUBER. It was known as sal mirabile Glauberi [1], was prepared from common salt and sulfuric acid, and was used medicinally as a laxative. Many kinds of spa water and the salts obtained from them contain sodium sulfate (e.g., Karlsbad salt, which contains 44 % sodium sulfate) [2].

Processes for the manufacture of soda and hydrochloric acid that developed in the 1800 s involved the production of sodium sulfate (salt cake) [3] (see Section 1.3.4). This method has now declined in importance compared to extraction from natural deposits and production as a byproduct of chemical processes. Byproduct sodium sulfate must be removed from wastewater for reasons of environmental protection, which allows largely closed recirculating systems to be established (e.g., for spinning baths in the viscose-fiber industry [4], [5]).

Sodium sulfate not only occurs in salt deposits in ancient geological formations but can also be produced on an industrial scale from continuously formed reserves in salt lakes in Canada, the United States, South America, the Commonwealth of Independent States, and other countries (see Section 1.3.3).

Figure 1. Solubility of sodium sulfate

Anhydrous sodium sulfate occurs naturally as thenardite, sometimes in high purity, and Glauber's salt occurs as mirabilite, $Na_2SO_4 \cdot 10\ H_2O$. In marine salt deposits and in the crystalline deposits that are being produced in salt lakes at the present time, many double salts containing

sodium sulfate occur such as astrakhanite, $Na_2SO_4 \cdot MgSO_4 \cdot 4\,H_2O$; glaserite, $Na_2SO_4 \cdot 3\,K_2SO_4$; glauberite, $Na_2SO_4 \cdot CaSO_4$; loeweite, $6\,Na_2SO_4 \cdot 7\,MgSO_4 \cdot 15\,H_2O$; d'Ansite, $MgSO_4 \cdot 9\,Na_2SO_4 \cdot 3\,NaCl$; vanthoffite, $MgSO_4 \cdot 3\,Na_2SO_4$; burkeite $Na_2CO_3 \cdot 2\,Na_2SO_4$; and hanksite, $KCl \cdot 2\,Na_2CO_3 \cdot 9\,Na_2SO_4$. Hence, the industrial production of sodium sulfate can be combined with the production of common salt, soda, or potash salts [6–10].

1.2. Properties

Physical Properties. Table 1 compares the properties of thenardite (anhydrous sodium sulfate) and Glauber's salt (the decahydrate). The heptahydrate, $Na_2SO_4 \cdot 7\,H_2O$, is unstable (Fig. 1) and can be detected on cooling saturated solutions to < 12 °C [11–13].

Table 2 lists the solubility of sodium sulfate in water [11], [12], [14–16]. Sodium sulfate is polymorphic; above 240 °C, four other modifications are formed from thenardite (Table 2) [14]. In the sodium sulfate – water system, a transformation occurs at a temperature that has been determined with great accuracy (32.384 °C) and is suitable as a fixed point. Above this temperature, anhydrous thenardite crystallizes from saturated solutions, and below it, Glauber's salt (Fig. 1).

The decrease in solubility of sodium sulfate resulting from the presence of sodium chloride can be utilized in the industrial production of sodium sulfate from aqueous solutions. This effect is shown by the three-component system sodium sulfate – sodium chloride – water (Table 3) [2], [17], [18].

The system sodium sulfate – sulfuric acid – water shows first an increase and then a decrease in the solubility of sodium sulfate with increasing sulfuric acid concentration [2], [15], [18]. The reaction to form sodium hydrogensulfate is of industrial importance (see Chap. 2).

The low solubility of sodium sulfate in organic solvents or mixtures of these with water can be used in the precipitation crystallization of thenardite [5], [15], [19] (Section 1.3.1).

Chemical Properties. In moist air, anhydrous sodium sulfate takes up water of crystallization with a considerable increase in volume, which reaches a factor of 4.17 on complete conversion to the decahydrate (Glauber's salt) and can lead to damage if the change occurs in cracks in buildings. Buildings constructed with cement, especially those made of concrete, can be destroyed by solutions containing sodium sulfate. Glauber's salt is not hygroscopic. It effloresces and is converted to an almost anhydrous sulfate after a few days in a cold current of air.

On heating below its melting point (884 °C), thenardite decomposes slowly. Above 1200 °C, the weight loss of the molten material can be several percent. If sodium sulfate is added to molten glass, sodium silicates are formed, and

1.3. Extraction and Production

Of the world production of sodium sulfate (ca. 4.6×10^6 t in 1988), approximately 50 % is a byproduct of the chemical industry, the remainder being extracted from natural deposits. World reserves of sodium sulfate are estimated at 3400×10^6 t [20], [21].

The extraction of sodium sulfate from wastewater from the chemical industry has a beneficial effect on the environment and has the further advantage that it is independent of weather conditions, in contrast to production from natural sources [5], [20]. Furthermore, the production plant is usually close to the consumer of the sodium sulfate, whereas production from natural deposits often takes place in remote regions.

Glauber's salt is not a commercial product, owing to its high content of water of crystallization (56 %) and consequently high transportation costs, its low melting point (32.4 °C), and its tendency to effloresce. However, it is an important intermediate product in many processes.

1.3.1. Crystallization and Calcination

The principle of the crystallization process is to cool the solution to < 20 °C, causing Glauber's salt, $Na_2SO_4 \cdot 10\,H_2O$, to crystallize [2], [22]. Multistage vacuum-cooled crystallizers are used, usually of the horizontal type.

Glauber's salt is recovered and calcined to form anhydrous sodium sulfate (thenardite) in the next stage. Glauber's salt "melts" in its own water of crystallization at 32.38 °C, forming a saturated solution of sodium sulfate that contains anhydrous sodium sulfate as a solid phase (37 % of the sodium sulfate from the Glauber's salt). In older processes, the saturated sodium sulfate solution, after removal of the precipitated sodium sulfate, was once again vacuum cooled, and the Glauber's salt that crystallized was again recovered and melted. If Glauber's salt was again crystallized from the residual mother liquor, up to 85 % of the total Glauber's salt could be recovered as anhydrous sulfate.

This energy-intensive process was superseded by evaporative crystallization of the saturated sodium sulfate solution obtained on melting Glauber's salt [23–28]. The energy consumption was reduced further by using multistage evaporation, in which the vapor was employed as heating steam for the following stage, which was operated at lower pressure. Further savings resulted from the use of mechanical or thermal compression of the vapor [29–31].

The formation of encrustations in the heat exchangers presented a problem, especially in the heat exchangers of the Glauber's salt melting vessels because of the decreasing solubility of sodium sulfate above 32 °C [2], [32]. For this reason, unheated melting vessels were often used, in which Glauber's salt was melted by mixing with approximately 15 times the amount of hot, saturated sodium sulfate solution from the evaporation stages [26].

The formation of encrustations can also be prevented if the heating medium for the melting vessel has such a low temperature (e.g., vapor from the last evaporation stage) that the temperature increase of the circulating melt solution in the heat exchanger is limited to 1 – 3 °C per pass [33].

In another process, part of the sodium sulfate solution is evaporated at 108 – 114 °C and pressures of up to 0.15 MPa absolute [34]. In this temperature range, the solubility curve of sodium sulfate exhibits a minimum, so that crust formation in the heat exchanger of the evaporator is greatly reduced. The vapor from this first stage is used as the heating medium for the evaporator of the second stage, which operates with vapor compression.

The purity of the sodium sulfate produced can be controlled by varying the amount of mother liquor removed at the calcination stage. Here, the saturation concentrations of the dissolved impurities must not be exceeded [35]. These processes can then yield a very pure sodium sulfate (> 99.9 %). The mother liquor can be fed to a biological wastewater treatment plant or worked up to yield Glauber's salt [36].

Figure 2 shows a flow diagram of a plant for the production of sodium sulfate from wastewater [5].

The formation of encrustations during the thermal dehydration of Glauber's salt can be largely prevented by the use of air, spray, or fluidized-bed dryers, which have no solid heat-exchange surfaces. For example, in the Holland evaporator, predried Glauber's salt is heated by combustion gases at 870 – 980 °C in a rotary dryer to produce thenardite. If the Glauber's salt is melted and thenardite is separated, the mother liquor can be spray-dried with hot combustion gases. The specific energy consumption can be reduced if molten Glauber's salt in the form of a crystal slurry is sprayed into a rotary dryer heated to 150 – 400 °C. In fluidized-bed drying, thenardite is produced with hot air at 450 °C, giving a waste gas temperature of 80 – 100 °C. The fines are recirculated, producing a dust-free sodium sulfate with a grain size that can be controlled up to 4.8 mm.

In these processes, the entire water of crystallization is evaporated, so that the impurities in Glauber's salt remain in the sodium sulfate [2], [37–39].

Sodium sulfate can be precipitated as thenardite from aqueous solutions by adding water-soluble organic solvents such as methanol [2], [40–43]. This process is used in the treatment of solutions containing Na_2SO_4 and sulfuric acid from the cellulose industry [44], [45].

Sodium sulfate can also be obtained from Glauber's salt by using submerged combustion heaters. However, the burner must be cleaned or changed frequently due to corrosion and encrustation [2], [20].

Sodium sulfate can be separated from mixtures of solid salts by flotation. This process is being investigated for the treatment of salt mixtures from natural deposits [46]

1.3.2. Production as a Byproduct of the Chemical Industry

Solutions of sodium sulfate are produced in numerous reactions of sodium compounds with sulfuric acid or with sulfur dioxide and oxygen. These solutions must be treated to prevent water pollution. Sodium sulfate is obtained from them by crystallization and calcination. The quantities of sodium sulfate produced as a byproduct from various sources depend very much on the state of the market for the main products and the state of the technology. In spite of this, total production of byproduct sodium sulfate has hardly changed since 1980 [20].

From Viscose-Fiber Spinning Baths. Fibers are produced by spinning viscose in a sulfuric acid precipitation bath in which the following reaction takes place:

$$2\,\text{Cell}-\text{OCS}_2\text{Na} + \text{H}_2\text{SO}_4 \longrightarrow 2\,\text{Cell}-\text{OH} + 2\,\text{CS}_2 + \text{Na}_2\text{SO}_4$$

Cell = cellulose

The precipitation bath contains ca. 10 % H_2SO_4, 20 % Na_2SO_4, and 1 % $ZnSO_4$. The spinning process produces ca. 1 kg of sodium sulfate for each kilogram of viscose fiber. Sulfuric acid must therefore be added continuously to the bath, and sodium sulfate removed [2], [4].

The treatment process for the bath consists of multistage evaporation, followed by cooling of the concentrated solution from 50 °C to 0 – 5 °C in a crystallizer. Glauber's salt is removed by centrifuges, and the mother liquor is recycled to the spinning bath. The zinc sulfate dissolved in the spinning bath does not crystallize. Thenardite containing 99.6 – 99.9 % sodium sulfate is produced by calcination of Glauber's salt in evaporating crystallizers with partial recycle of the mother liquor [23], [47–50]. In Western Europe in 1988, 305 000 t of sodium sulfate was produced from viscose-fiber manufacture, and in the United States in 1989, 89 000 t [20].

From Sodium Dichromate Production. Sodium sulfate is produced by the acidifica-

tion of sodium chromate solution with sulfuric acid according to the equation:

$$2\,Na_2CrO_4 + H_2SO_4 \longrightarrow Na_2Cr_2O_7 + Na_2SO_4 + H_2O$$

If the reaction is carried out above 32.4 °C, thenardite (> 99 % Na_2SO_4) precipitates. This still contains 0.2 % dichromate, which can be removed by dissolving, reducing with SO_2, and filtering off chromium (III) oxide. If the sodium sulfate is used in the sulfate cellulose (Kraft) process, the dichromate is reduced and therefore does not cause problems [21], [51,52].

Quantities of sodium sulfate obtained from sodium dichromate production in 1988 – 1989 were 70 000 t/a in western Europe and 110 000 t/a in the Unites States [20].

From Ascorbic Acid Production. In the synthesis of ascorbic acid by the Reichstein – Grüssner process, sulfuric acid is used in the production of the diacetone-L-sorbose intermediate. The sulfuric acid is neutralized with sodium hydroxide solution in a later stage of the process [53]. On removal of the solvent, a saturated solution of Na_2SO_4 is produced, from which thenardite (> 99.9 % Na_2SO_4) is obtained by evaporative crystallization. For each tonne of ascorbic acid, 1.5 t of sodium sulfate is produced. In 1988 – 1989, 45 000 t/a Na_2SO_4 was produced in this way in western Europe, and 17 000 t/a in the United States [20].

From Other Processes. Sodium sulfate is also produced in various quantities from a large number of other chemical processes (Table 4).

1.3.3. Production from Natural Sources

The most important production plants for sodium sulfate from natural sources are located in Canada, Spain, Mexico, Turkey, the United States, and the CIS. The output from these countries in 1987 – 1989 was ca. 2×10^6 t/a [20].

Owing to the varying compositions of the salt mixtures in the deposits, many types of processes for the production of sodium sulfate and other compounds have been developed [2], [46], [72,73]. A review of some important production methods is given here.

Production in Canada. The Canadian deposits are located in Alberta and Saskatchewan, and are in the form of shallow lakes with only a few inlets. These contain sodium sulfate in the form of brines or deposits of mirabilite ($Na_2SO_4 \cdot 10\,H_2O$). Mirabilite dissolves from the deposits to an extent that depends on annual temperature variations, amount of water entering the lake, and evaporation. Various processes are used to recover the product.

Brine is pumped into shallow basins, from which some of the water evaporates during the summer. In winter, mirabilite crystallizes (ca. 600 kg/m^3 brine) and collects at the bottom of the basin. Excess brine is pumped back into the lake. Mirabilite is then collected by means of drag lines or other equipment and taken for further treatment.

Other operations use floating dredges to mine permanent deposits of mirabilite from the lake beds. The slurry of mirabilite and brine is sent by pipeline for further treatment.

In a third method, brine is produced by dissolving the salt in situ with hot water, which is injected via a large number of boreholes into the body of salt lying under the brine. The solution produced is taken to the next stage of treatment, which consists of precipitating crude salt in cooling towers [2], [20], [72], [74,75].

In some cases, dry deposits of mirabilite are mined conventionally, and the crude salt can then be transported to the processing plant.

The crude salt is charged into evaporators, where it "melts" in its own water of crystallization. The crystal suspension is then evaporated with hot combustion gases and transported to rotary dryers by belt conveyors.

In operations that send a brine for processing, Glauber's salt is crystallized by cascading the brine in contact with cold air [20], [75]. Entrained clay slime can be removed in centrifuges. The Glauber's salt melt is then evaporated by the submerged combustion of natural gas. Sodium sulfate (97 – 99.8 % Na_2SO_4) with a controlled grain size is produced by grinding and screening. Total production in Canada in 1987 – 1988 was 312 000 t/a sodium sulfate [20].

Production in Spain. Glauberite deposits are mined in the provinces of Burgos, Toledo, and Madrid. The Castellar mine at Toledo produces a crude salt containing 67 % Na_2SO_4,

19 % $CaSO_4$, and 12 % clay and shale, from which sodium sulfate can be produced in various ways [2], [7], [76], [77]. For example, sodium sulfate can be leached from the crude salt at 35 – 40 °C (stage 1). The residue contains slime (clay) and glauberite ($Na_2SO_4 \cdot CaSO_4$), which is stable above 29 °C. Below 29 °C, this solid material yields additional sodium sulfate solution, which is recycled to the first stage. Thenardite is produced from the leachate by vacuum evaporation. The three deposits yielded 510 000 t of sodium sulfate in 1988 [20].

Production in the United States, Mexico, Turkey, and the Commonwealth of Independent States. Sodium sulfate is obtained from natural deposits in California, Texas, and Utah.

Brine containing sodium carbonate is obtained by sinking wells into the deeper layers below the salt crust of Searles Lake in California. The brine is treated with carbon dioxide to precipitate sodium hydrogencarbonate, from which sodium carbonate is obtained. The filtrate is then cooled to 15 °C to precipitate borax, which is filtered off. Further cooling to 5 – 6 °C causes Glauber's salt to crystallize. The decahydrate still contains some finely divided borax, which can be removed by hydraulic screening. Only Glauber's salt with a grain size of > 0.8 mm is dehydrated to form thenardite. The fine crystals are used as crystallization seeds [2], [20], [72], [78]. In 1989, 218 000 t of sodium sulfate was produced.

In Texas, brine from deposits close to the surface is treated. In Seagraves, Glauber's salt is separated from brine saturated with sodium chloride at −7 to −10 °C. The product obtained is melted and evaporated by submerged gas burners to produce thenardite. The thenardite suspension is centrifuged and dried to yield a product containing 99.7 % Na_2SO_4 [2], [20], [72], [79]. In 1989, ca. 140 000 t of sodium sulfate was produced by this method [20].

A sodium sulfate production plant in Utah uses brine from the Great Salt Lake. The brine is pumped into solar evaporation ponds with a surface area of ca. 80 km^2. Each year, stepwise crystallization of sodium chloride, potassium salts, and Glauber's salt takes place. These are removed by scrapers and transported by road vehicles for treatment. The crude salt is dissolved, the saturated solution is filtered, and sodium chlo-

ride is added to precipitate thenardite, which, after filtration and drying, contains $>94\,\%$ Na_2SO_4. Recrystallization gives thenardite containing $>99.7\,\%$ Na_2SO_4 [2], [6], [20], [80]. In 1989, 25 000 t of Na_2SO_4 was produced [20].

Sodium sulfate production figures for Mexico, Turkey, and the former Soviet Union are listed in Table 5.

1.3.4. Production of Sodium Sulfate

In addition to production methods based on byproduct material or natural deposits of sodium sulfate, processes are also operated in which sodium sulfate is manufactured from compounds that contain sodium and sulfate.

Production from Sodium Chloride and Sulfuric Acid (Mannheim Process). The thermal reaction

$$2\,NaCl + H_2SO_4 \longrightarrow Na_2SO_4 + 2\,HCl$$

which takes place via the intermediate formation of sodium hydrogensulfate, was developed as part of the Leblanc sodium carbonate process [3]. The reaction produces sodium sulfate and hydrogen chloride, which are of comparable economic importance [20].

This process is often carried out in Mannheim furnaces [2], [21], [63], [81, 82], which have a diameter of 6 m and produce 25 t/d sodium sulfate and 37.5 t/d hydrochloric acid (31 %) by addition of 93 – 96 % sulfuric acid to sodium chloride. One tonne of sulfate requires 3.6×10^6 kJ (88 kg of fuel oil), 65 kW · h, 1.4 m^3 of process water, and 26 m^3 of cooling water. The product contains 97 – 99.7 % Na_2SO_4. The small amounts of free sulfuric acid in the product are neutralized during cooling in a rotary cooler by the addition of sodium carbonate. The commercial product is obtained by grinding and screening.

The Climax Chemical Co., United States, operates a plant in which sodium chloride and sulfuric acid are reacted by the Cannon fluidized-bed process. Production costs are lower than with the furnace process [2], [20], [83].

In 1988 – 1989, ca. 390 000 t/a sodium sulfate was produced from sodium chloride and sulfuric acid [20].

Sodium sulfate can be produced from dilute sulfuric acid and sodium chloride in a spray evaporator [62], [84].

Production by the Hargreaves Process. Up to 1983, the Morton Chemical Co. in Louisiana, United States, operated the Hargreaves process, which is based on the reaction

$$4\,NaCl + 2\,SO_2 + O_2 + 2\,H_2O \longrightarrow 2\,Na_2SO_4 + 4\,HCl$$

This process is of interest owing to its low energy consumption compared to other production processes. Mannheim furnaces were used for the reaction, but rotary kilns or fluidized-bed reactors have been proposed [2], [20], [82], [85–87].

Production by Metathesis. Several processes have been developed for the conversion of sodium chloride to sodium sulfate, for example,

$$2\,NaCl + MgSO_4 \longrightarrow Na_2SO_4 + MgCl_2$$

Of these processes, the reaction of sodium chloride with kieserite ($MgSO_4 \cdot H_2O$) is the most important, because of all the crude salts from German potash production, kieserite is the cheapest source of sulfate.

To obtain a good yield of Glauber's salt, it is important to have the optimum $NaCl/MgSO_4$ ratio in the starting liquor. In the five- component system $Mg-Na_2-SO_4-Cl_2-H_2O$, an optimum point exists for the composition of the starting liquor. During dehydration of Glauber's salt, sodium chloride is added to the mother liquor, causing thenardite to precipitate. The mother liquor can then be used to produce the starting liquor. The process produces thenardite containing 98.7 – 99.5 % Na_2SO_4 [2], [6], [40], [88–90]. In 1988, ca. 118 000 t of Na_2SO_4 was produced [20].

1.4. Exploitation of Byproduct Sodium Sulfate

Sodium sulfate is produced in a number of chemical processes (see Section 1.3.2) and must be utilized or disposed of. Hence, processes for converting sodium sulfate into its constituents (sodium hydroxide and sulfuric acid) or into other useful chemicals are of interest [5], [20].

Table 5. Production of sodium sulfate in Mexico, Turkey, and the Soviet Union in 1987 – 1988

Country	Starting material	Sodium sulfate production, t/a	References
Mexico	Brine from salt lakes	420 000	[20]
Turkey	Crude salts from salt lakes	157 000	[20]
Soviet Union	Water from the Caspian Sea, etc.	375 000	[20], [72]

1.4.1. Electrochemical Decomposition of Sodium Sulfate

The electrochemical decomposition of sodium sulfate takes place according to the overall reaction:

$$2\,Na_2SO_4 + 6\,H_2O \longrightarrow 2\,H_2SO_4 + 4\,NaOH + 2\,H_2 + O_2$$

The anodic decomposition of water produces H^+ ions and oxygen

$$2\,H_2O \longrightarrow 4\,e^- + 4\,H^+ + O_2$$

and the corresponding cathodic reaction produces OH^- ions and hydrogen

$$2\,H_2O + 2\,e^- \longrightarrow 2\,OH^- + H_2$$

If sodium hydroxide solution and sulfuric acid are required, reverse reaction between H^+ and OH^- must be prevented. This can be achieved by using a mercury cathode or a diaphragm cell [5].

Figure 3. Decomposition of sodium sulfate by electrodialysis

The use of cation- and anion-selective ion-exchange membranes has led to new developments. Figure 3 shows the principle of Na_2SO_4 decomposition by electrodialysis in a cell divided into three zones by a cation-exchange membrane (CM) and an anion-exchange membrane (AM). The sulfate solution flows through the central zone. Sodium hydroxide and hydrogen are formed in the cathode space, and sulfuric acid and oxygen in the anode space. Sulfuric acid (5 – 15 wt %) and sodium hydroxide (15 – 20 wt %) are obtained with an energy consumption of 3500 – 4000 kW · h/t NaOH and a current efficiency of 60 – 80 %. The consumption of electrical energy can be reduced by using the reaction gases H_2 and O_2 in a fuel cell, or by the use of electrodialysis cells with gas-diffusion electrodes [91], [92].

Further improvements in electrodialysis are achieved by using anion-exchange membranes composed of styrene – divinylbenzene copolymer with strongly basic quaternary ammonium groups and a hydronium ion blocker. This gives improved current efficiencies and more concentrated sodium hydroxide and sulfuric acid [93].

Figure 4 shows a two- compartment cell divided by a cation-exchange membrane. The sulfate solution is charged into the anode space where it becomes enriched in sulfuric acid; only salt- containing acid can be produced. The sodium hydroxide in the cathode space is almost free of sulfate [94]. As the acid concentration increases and the salt concentration decreases, more H^+ ions contribute to the transport of current. Therefore, the current efficiency depends not only on the selectivity of the membrane and the sodium hydroxide concentration in the catholyte, but also on the H^+/Na^+ ratio in the anolyte. High current efficiencies are obtained only with an excess of Na^+ ions. For example, if the molar H^+/Na^+ ratio in the anolyte is 1 : 1, 5 – 10 % sulfuric acid and 15 – 25 % sodium hydroxide are obtained with current efficiencies of 65 – 70 %. Electrolysis of highly concentrated sodium sulfate solutions (up to 39 % Na_2SO_4) gives sulfuric acid concentrations of 10 – 20 %

and a sodium hydroxide content of 15 – 20 % with current efficiencies of 65 – 80 % [95].

In the Sulfomat process, sodium sulfate is electrolyzed to give sodium sulfate- containing sulfuric acid and caustic soda solution. The latter is used for absorption of SO_2 in flue gas desulfurization, giving a solution of sodium sulfite. Acidification with the Na_2SO_4-containing sulfuric acid gives SO_2 and reforms sodium sulfate, which is electrolyzed [96]. Also, spinning bath solutions from the viscose-fiber industry can be regenerated electrochemically [97], [98].

Figure 4. Electrolysis of sodium sulfate solution

Figure 5. Electrodialysis of sodium sulfate with bipolar membranes

A development by Allied Signal of electrodialysis with bipolar membranes is of interest due to the low energy consumption [99–102]. In these bipolar membranes (BM), a cation-exchange membrane is bonded to an anion-exchange membrane [103]. Water molecules diffuse to the phase boundary CM – AM, where they dissociate in the electric field. The H^+ and OH^- ions diffuse in opposite directions. If the bipolar membranes are combined with CM and AM, as shown in Figure 5, the sulfate can be decomposed without the formation of hydrogen and oxygen. A large number of individual BM – AM – CM elements can be fitted between the two end electrodes. Decomposition of H_2O at the electrodes is then negligible. The only energy required is the dissociation energy of the water (0.022 kW · h/mol). Laboratory investigations showed an energy consumption of 1450 – 1700 kW · h/t NaOH when 12 – 16 % sodium hydroxide and 5 – 10 % sulfuric acid are produced. Allied Signal supplies cells for pilot- and full-scale operation.

1.4.2. Conversion Processes

Metathesis with Hydrogen Chloride. Owing to the high cost of electricity in the sodium sulfate electrolysis process, early attempts were made to bring about metathesis with hydrogen chloride:

$$Na_2SO_4 + 2\,HCl \rightleftharpoons 2\,NaCl + H_2SO_4$$

If the reaction is carried out in 40 – 60 % sulfuric acid, sodium chloride precipitates and can be obtained in 99.2 % yield (with 40 % H_2SO_4 at 30 °C) [5], [52][104–106]. The concentrations must be such that enough HCl is taken up by the reaction mixture. A stoichiometric amount of HCl is sufficient for the reaction to proceed. Of this, approximately one-third distils off during the process, and must be recycled to the reactor.

The sodium chloride obtained can be used for the chlor-alkali electrolytic process [105]. The 40 – 60 % sulfuric acid produced in the industrial process contains 1 – 2 % residual Na_2SO_4 [105] and is preferably recycled to the process in which the sodium sulfate is formed or used for reactions with sodium compounds, such as the production of chlorine dioxide from sodium chlorate, whereby Na_2SO_4 is reacted continuously with HCl in a decantation – washing column [107].

The metathesis of Na_2SO_4 with HCl in dilute sulfuric acid was carried out in 1951 in a pilot plant [105]. Carrying out the metathesis at 800 – 900 °C in a melt allows pure sulfuric acid and pure sodium chloride to be obtained [108].

Conversion to Potassium Sulfate. The reaction

$$Na_2SO_4 + 2\,KCl \longrightarrow K_2SO_4 + 2\,NaCl$$

has been thoroughly investigated [5], [77], [109], [110]. It occurs in two stages: In the first stage, glaserite ($Na_2SO_4 \cdot 3\,K_2SO_4$) is formed, which is decomposed by more potassium chloride to form K_2SO_4 and NaCl in the second stage:

$$Na_2SO_4 \cdot 3\,K_2SO_4 + 2\,KCl \longrightarrow 4\,K_2SO_4 + 2\,NaCl$$

The reactions can be carried out at 20 – 40 °C. If Glauber's salt is used, temperatures of > 32 °C are preferred. In a modern plant, K_2SO_4 yields of 98 – 99 % are obtained [111], [112]. The reaction – crystallization process is carried out in a loop-type bubble column [113].

The process has been operated since1984in a Russian plant that consumes 40 000 t/a Na_2SO_4. The Potash Corporation of Saskatchewan (PCS) has operated an experimental plant since 1985 in Cory, Canada, with a consumption of 25 000 t/a Na_2SO_4 [20], [112]. Single-stage processes for carrying out this reaction have been proposed [114], [115].

1.4.3. Reduction Processes

Sodium sulfate can also be used in reductive processes (Table 6).

1.5. Uses

World consumption of sodium sulfate in 1987 was ca. 4.6×10^6 t [20].

The most important consumers were the cellulose-fiber industry and manufacturers of glass and detergents (Table 7).

Other users are from a wide range of industries [2], [20], including dyeing technology [132], electrochemical metal treatment [133], animal feeds [2], heat accumulators [20], and sponge manufacture [20].

1.6. Quality Specifications and Analysis

The highest standards of quality and whiteness are required for the detergent, textile, and animal feed industries. For use as a refining agent in glass smelting, the iron content of sodium sulfate must be low. For the sulfate cellulose (Kraft) process, a purity of 96 – 98 % is adequate. Typical analysis figures are given in [2].

The specification in DAB 9 [134] sets the following maximum impurity levels in anhydrous sodium sulfate: chloride 450 ppm, calcium 450 ppm, iron 90 ppm, arsenic 5 ppm, heavy metals 45 ppm, and water 5 %.

Standard methods of analysis of sodium sulfate for industrial use are as follows:

ISO 3234-1975	weight loss on heating to 110 °C
ISO 3235-1975	fraction insoluble in acid
ISO 3236-1975	chloride content (mercurimetric)
ISO 3237-1975	sulfate content, calculation and gravimetric method (as barium sulfate)
ISO 3238-1975	calcium content by the EDTA complexometric method
ISO 3239-1975	iron content by photometry with 1,10-phenanthroline
ISO 3240-1975	acid or alkali content
ISO 3241-1975	pH by potentiometric method
ISO 5142-1977	sodium sulfate content, gravimetric method
ISO 5994-1979	calcium content by atomic absorption spectroscopy

1.7. Occupational Health and Environmental Protection

Sodium sulfate is a permitted food additive [135] and is a common component of spa waters [2].

Inhalation of sodium sulfate dust causes irritation of the mucous membranes, and prolonged skin contact has a drying effect. The laxative effect of oral ingestion is well known and is used medicinally.

Sodium sulfate in wastewater can be recovered as thenardite (Section 1.3.2). However, if the solutions are very dilute (< 5 % Na_2SO_4), the crystallization process is energy intensive. In such cases, treatment of the wastewater by a membrane process [136], a precipitation process [137], or by biochemical methods [36] can be considered.

1.8. Economic Aspects

Demand for sodium sulfate in the Western industrialized nations has decreased during the 1980s, but further reduction is expected to be balanced by increasing consumption in other parts of the world. The cellulose and glass industries and detergent manufacture account for ca. 80 % of the

Table 6. Use of sodium sulfate for reduction processes

Process	Reaction	References
Leblanc process	$Na_2SO_4 + 2\,C + CaCO_3 \longrightarrow Na_2CO_3 + CaS + 2\,CO_2$	[5], [11], [116]

sodium sulfate consumed. Environmental regulations have a great influence on the market for sodium sulfate, affecting both its production and its consumption. Owing to the large natural reserves of sulfate and the large quantities produced as a byproduct of the chemical industry, prices are not expected to increase greatly. The most important producing countries in 1988 were the United States 16 %; the Soviet Union 14 %; Spain 13 %; Mexico 10 %; Canada 7 %; Japan 6 %; and Belgium 6 %. The remaining 28 % came from a number of sources [20].

2. Sodium Hydrogensulfate

Sodium hydrogensulfate [138] occurs as the monohydrate, $NaHSO_4 \cdot H_2O$, in the system sodium sulfate – sulfuric acid – water [15], [18] or exists as the solid phase $NaHSO_4$ at a sulfuric acid concentration of 62 %. The monohydrate is converted to the anhydrous salt at 58.45 ± 0.05 °C.

The thermal decomposition represented by the equation

$$2\,NaHSO_4 \rightleftharpoons Na_2S_2O_7 + H_2O$$

takes place near the melting point, which can be determined only approximately (ca. 183 °C) with a water vapor pressure of 2500 Pa (25 mbar). Conversion to sodium disulfate is complete after heating for ca. 4 h at 240 – 260 °C. Sodium disulfate decomposes above 400 °C to form sodium sulfate with liberation of sulfur trioxide.

Production. Sodium hydrogensulfate is formed as an intermediate in the production of hydrochloric acid by the Mannheim process (Section 1.3.4) and is a byproduct of the manufacture of chromium(VI) oxide [51], [56], [63], [139]. The reaction between sulfuric acid and sodium chloride may be carried out by the old process using cast iron retorts heated with gas or oil, or by the use of submerged combustion equipment in brick-lined vessels [82], [140]. The addition of a stoichiometric amount of sulfuric acid to sodium sulfate or Glauber's salt at 200 – 280 °C produces molten sodium hydrogensulfate [141]. The same reaction can be utilized to produce sodium hydrogensulfate in aqueous solution at 80 °C directly [141].

Uses. Sodium hydrogensulfate is used in the manufacture of household cleaners, in the textile industry, for the regeneration of rubber, for metal surface treatment, and as a flux for low-melting metals and their alloys [2].

1. Introduction

1.1. Concerning the Importance of Solar Energy Conversion

About 78 % of the world's current energy supplies are based on fossil energy sources; the remaining primary energy is provided by hydropower (5 %), firewood/biomass (13 %) and nuclear energy (4 %) [1]. The following structurally inherent problem areas of such an energy supply will become increasingly evident:

1) Exponential growth of CO_2 levels in the atmosphere, leading to the threat of a worldwide climatic change (anticipated mean temperature increase of 2 – 4 K for a doubling of CO_2 concentration [2]). The World Climate Conference held in Toronto in 1988 already recommended a global reduction in CO_2 emissions of 50 % by the middle of the next century.
2) Cheap fossil energy sources will in the long term become only limitedly available; furthermore, these resources, particularly oil, are distributed very unevenly worldwide.
3) Exploitation of nuclear energy does not appear to be socially acceptable.
4) The problem of energy provision in the Third World remains unsolved, particularly in decentralized regions (one example: at the present time more than 10^9 persons have no access to electrical energy for lighting, heating, cooking, TV, etc. [3]).

If it is assumed that the exploitation of fossil energy sources will have to be drastically reduced in the future and that nuclear energy (including fusion) will not be a feasible option for the worldwide provision of energy, two alternative energy sources will have to be vigorously pursued:

1) Rational use of energy
2) Renewable energy sources

In European industrialized countries it is acknowledged that the virtual resource of "efficient energy utilization" represents potentially about 50 % of present-day energy consumption [4].

The following simple calculation illustrates the considerable potential of terrestrial solar energy utilization:

The total mean solar radiant flux at sea level is 10^{17} W. If it is assumed that, on average, this solar input is converted with an efficiency of 10 % into final energy, then with a global areal utilization of 0.5 %, 5×10^{13} W of technically utilizable power will be available. With a future world population of 10^{10} people this would mean an average value of 5 kW per head. This corresponds roughly to the current mean value of energy consumption in western Europe.

This numerical example is simply intended to illustrate the potential of renewable energy sources with the example of the direct utilization of solar energy. Water power, wind energy, biomass (principally utilization of waste), etc., will contribute substantially to a nonfossil fuel energy supply.

The next development stage of the energy supply system, avoiding the aforementioned problem areas, could therefore have the following outline structure:

1) More intelligent handling of energy
2) Extensive utilization of renewable energy sources
3) Residual utilization of fossil energy sources

A residual utilization of fossil resources at an ecologically acceptable level is envisaged in

order to be able to compensate to some extent variations, e.g., in solar energy supplies (see Section 1.4).

Obviously, thorough investigations must be carried out to ensure that such a new energy system does not lead to problems. In this connection, some characteristic features of solar energy conversion will be mentioned:

Figure 1. Spectral irradiance as a function of wavelength and photon energy. The parameter AM is explained in Figure 2

Pollutants. Solar energy conversion is not based on chemical or nuclear fuels, and therefore in principle no harmful waste products such as CO_2, NO_x, radioactive waste, etc., are produced during operation of the energy converters. Potential environmental pollution may occur in the context of a solar energy technology – as is common with any technical production – in the manufacture of technical components (e.g., solar cells). The relevant processes must be suitably optimized and the actual production stage must be carefully controlled. The recyclability of the extensive converter systems must be taken into account.

Areal Requirements. Solar energy conversion is characterized by a relatively small energy flux density (see Section 1.2), which inevitably means a large-area energy conversion technology. The requisite areas can, however, be realized to a considerable extent on existing buildings and transportation facilities (in Germany ca. 10 % of the total area); additional energy conversion areas would have to be distributed among a large number of small units.

Change in Global Energy Fluxes. The albedo (nondirectional reflectance) for solar radiation at the converter sites would on average be reduced by the introduction of a large-scale energy conversion program which leads in principle to local heating. Quantitatively, this change in atmospheric energy fluxes is at most a few thousandths; the effects will therefore be negligible compared to other anthropogenic effects, as long as largely the installation of distributed small-scale converter systems is adopted.

1.2. Terrestrial Solar Radiation

The radiation properties of the sun and the geometry of the solar-terrestrial system result in an irradiance of

$$E_{\mathrm{sc}} = 1367 \pm 1\,\% \,\mathrm{W/m^2}$$

at the top of the Earth's atmosphere (at the time of the equinoxes) [5]; where E_{sc} is termed the solar constant. The associated extraterrestrial spectrum (Fig. 1) can be satisfactorily approximated by a Planck radiator with $T = 5777$ K. The extinction of the solar radiation in the atmosphere is roughly a function of the parameter "air mass" (AM) (Fig. 2). Spectra for AM 0 and AM 1.5 are shown in Fig. 1.

Figure 2. The parameter "air mass" (AM) is defined as the relative path length of solar beam radiation through the atmosphere (AM = 0 characterizes extraterrestrial situations)

The shape of the terrestrial solar spectrum has a considerable influence on the conversion efficiency of technologies that require photons with energies above a threshold value (photovoltaics, photochemistry).

In a clear atmosphere and under AM 1.5 conditions, maximum irradiances of about

$$E_{\max} \approx 1000\,\mathrm{W/m^2}$$

occur on the Earth's surface. Mean values of the solar radiant flux densities for three typical sites are given in Fig. 3. The relatively low energy densities in the range of a few hundred watts per m^2 are the reason why a large-scale solar energy utilization will always also be a "large-area technology" (see Section 1.1).

Figure 3. Means values of solar irradiance for Phoenix, United States (33.4 °N, upper curve), Ispra, Italy (45.8 °N), and Hamburg, Germany (53.6 °N, lower curve). Data for south-facing tilted planes (tilt angle equal to the latitude of the site); averaging period: 20 d

The mean annual radiation level at a radiation-favorable desert site and at a site in central Europe differ only by a factor of 2 (Fig. 3). Substantial differences are found however in the seasonal variation of the radiation intensity: The maximum to minimum mean value is 1.5 : 1 and 15 : 1, respectively. These seasonal changes in the solar energy supply necessitate the use of long-term energy storage systems or complementary, energy-producing systems that can be regulated (e.g., residual, fossil-fueled plants), at least in higher latitudes (see Section 1.4).

On account of the scattering of light in the atmosphere the global (total) radiation E_g at the Earth's surface consists of a diffuse component E_d and a beam component E_b. The E_d/E_g ratio for the three sites in Figure 3 is illustrated in Figure 4. Because of thermodynamic principles, the diffuse radiation – as long as the frequency of the light is not changed – cannot be concentrated. This means that conversion technologies that use lenses or mirrors to concentrate the radiation can be used only under unfavorable conditions at higher latitudes, in which the E_d component is as a rule more than 50 %.

Figure 4. Ratio of diffuse radiation to global radiation for the data sets shown in Figure 3 (upper curve: Hamburg, lower curve: Phoenix, middle curve: Ispra)

1.3. Methods of Solar Energy Conversion

The methods that can in principle be used to convert solar radiation into technically utilizable energy may be subdivided into three categories:

1) Photothermal conversion
2) Photovoltaic conversion
3) Photochemical conversion

In *photothermal methods* solar radiation is absorbed by optically broad-band absorbers (typically: $\lambda_{abs} = 0.3 - 2\,\mu m$); the energy of the photons is converted into thermal energy. Depending on the quality of the insulation of the absorbers, fluid output temperatures of about 20 – 150 K above ambient temperature can be achieved with good energy efficiencies without optical concentration. Systems with moderate concentration reach useful temperatures of up to 800 K, while highly-concentrating methods reach temperatures of 1500 K and above.

Solar thermal energy conversion has broad areas of application, ranging from domestic heating, to industrial process heat generation, e.g., for cooling, distillation and drying; electrical energy can be provided on a large scale through solar thermal power-stations. *Passive solar energy conversion* for heating buildings, in which parts of structural bodies serve as radiation absorbers and energy storages, is technically particularly elegant.

Photovoltaic (PV) energy conversion involves the direct conversion of photon energy into excitation energy of electrical charge carriers. In semiconductor solar cells, e.g., of silicon, current densities of 300 A/m^2 at a voltage of

0.5 V can be achieved with optically nonconcentrating systems.

Applications of photovoltaic energy converters range from consumer products (pocket calculators), through decentralized autonomous power supplies (telecommunications, domestic power supply, drinking water pumps) to utility-grid-coupled PV units for power generation in conjunction with conventional power stations.

Technically perfected systems already exist for photothermal and photovoltaic energy conversion. There are areas of application in which the use of these techniques is already economically viable. In contrast to this, *photochemical* energy conversion is still in the basic research stage. With this type of conversion the chemical potential of reactants is increased by the direct absorption of photons (for example photosynthesis). A main problem of photochemical conversion is the low energy of the photons of the solar spectrum compared to most chemical excitation energies (see Fig. 1).

Further interesting ways of using solar energy can be obtained by combining the three methods discussed above. An example is the coupling of PV electricity and solar process heat in a high-temperature electrolysis process (reduction of the electrolysis voltage via heat input).

Reference may be made to [5] with regard to a thermodynamic treatment – particularly an exergy analysis – of the various energy conversion processes.

1.4. Matching of Solar Energy Production and Consumption

All energy supply systems have to solve the problem of the temporary matching of consumption and production. The conventional methods for solving this problem are:

1) Control of production
2) Load management
3) Influencing the structure of consumption
4) Storage devices

In the conventional heating and transportation sector there is a substantial temporary decoupling – at least when fossil, readily storable energy carriers are used – between the provision of energy and its utilization. In the electricity supply sector and in the utilization of waste heat (e.g., from combined heat and power units) the aforementioned methods have to be used more intensively.

In contrast to end energy production from fossil resources, energy provision from solar sources cannot be regulated. The variations in the energy supply are, however, not of a purely random nature, and indeed are largely governed by the deterministic diurnal and seasonal fluctuations.

Just as conventional energy systems have matched consumption – via the measures (2) and (3), to a production that is as constant as possible over time – a future energy supply system based largely on solar sources consumption would have to be adapted to the deterministic time behavior of the solar energy supply. Two simple examples of possible measures are the large-scale introduction of electric cars with charging phases preferably during the midday period, and the use of cooling units with an integrated cold store; both the vehicle charging stations as well as the operation of the cooling units could be remotely controlled from energy distribution centers.

In the case of electricity supply the random fluctuations in solar energy can be counteracted by a linked arrangement of spatially dispersed energy converter systems. The correlation of radiation fluctuations at various locations decays to a first approximation according to $\exp(-a \cdot r/T)$, where r is the distance between two converters, T is the period of the fluctuations, and a is a constant [6]. (This formula applies to roughly homogeneous climatic regions and periods of less than a few hours). In real large-area networks (1000×1000 km) random variations in the hour range are consequently largely statistically compensated. A precondition for this is of course a bidirectionally operating electricity grid. The remaining fluctuations could be covered, at least statistically, by energy-weather forecasts [7]; load management and the control of complementary, for example, fossil fueled power-stations, could thus be considerably simplified.

In situations of high shares of fluctuating solar electricity in utility grids (in central Europe from 20 – 30 % [4]), storage systems or extensive load management techniques are required to trap the solar energy production peaks. In ad-

dition to water power reservoirs, hydrogen systems in particular are suitable for this purpose [8].

A large-scale energy distribution is difficult to implement in the heat supply sector. On the other hand, in this sector the construction of storages ranging from small day reservoirs up to seasonal reservoirs is technically more favorable than in the electricity supply sector. Storages based on sensible heat (water) belong to the state of the art, whereas chemical heat reservoirs (e.g., sorption and phase transition reservoirs) are in the developmental stage [9].

On the basis of the measures outlined above for compensating or overcoming solar radiation fluctuations, future energy supply systems – including those for industrialized countries in central latitudes – are conceivable, which utilize for example the following energy sources [4]:

1) Rational energy utilization 40 %
2) Renewable energy sources 30 %
3) Utilization of fossil energy sources 30 %

The figures given are simply percentage values for scenarios that appear reasonable at the present time, and do not represent limiting values. In particular, the residual utilization of fossil energy sources could be reduced still further if large-scale energy storages or extensive load management strategies were used.

2. Solar Thermal Energy

2.1. Development and Historical Aspects

In the early advanced civilizations, the sun was worshipped as a divine being who provided light and warmth. Around 700 B.C. vestal virgins lit the sacred fire by using focused sun rays and the Incas prepared their holy meal with the help of simple reflectors. About 3000 years ago, the ancient Egyptians illuminated the underground passages and burial chambers of their kings with sunlight by using complicated mirror systems. Solar architecture originated in Greece: The philosopher SOCRATES (399 B.C.) imagined his ideal house to be cool in summer and warm in winter. While planning residential buildings, the Greek town planners and architects in the 4th and 5th century B.C. took into account that the path of the sun in summer is different to that in winter. They also constructed the heat storing masses required for the passive utilization of solar energy in the form of solid inner walls made of clay bricks.

The Greek philosopher ARCHIMEDES (287 – 212 B.C.) is supposed to have set fire to hostile Roman ships in 212 B.C. in the harbor of Syracuse by concentrating sun rays with mirrors. It was not until the 17th and 18th century that physicists, mathematicians, and engineers started scientific experiments on the utilization of solar energy. The renaissance of the focusing mirror began with ATHANASIUS KIRCHER (1601 – 1680) who in 1639 proposed that focusing mirrors with large focal lengths could be constructed from several plane mirrors. In 1686, the German mathematician E. W. VON TSCHIRNHAUS (1651 – 1708) successfully produced metal mirrors of ca. 160 cm diameter from polished sheet copper. With these mirrors, he was able to boil water, melt tin and lead plates in a few minutes, and vitrify bricks and clay pieces. In the 18th century, the French scientist G. L. LECLERC CONTE DE BUFFON (1707 – 1788) conducted extensive experiments with large reflectors of different sizes made from ca. 130 to 360 individual plane mirrors. To prove ARCHIMEDES's experiment, he used his mirror system to burn wood from a distance of 50 to 60 m. The next hundred years saw the continuation of experiments with focusing mirrors and the construction of various types of solar ovens.

In Tours in 1866, the French mathematics professor A. B. MOUCHOT was successful in realizing the first solar thermal power plant (a steam engine driven by solar energy). In the years that followed, he improved the reflectors and receivers and developed automatic tracking systems. At the World's Fair in Paris in 1878, MOUCHOT and his assistant A. PIFRE presented a printing press which was driven by solar energy. Sunlight was concentrated on an evaporator by using a concave mirror with a diameter of 5 m. The steam formed was expanded in a steam engine which drove the printing press (Fig. 5).

The Swiss natural scientist H. B. DE SAUSSURE (1740 – 1799) constructed the first hot box in 1767. It consisted of five glass boxes of different sizes that were placed one inside the other on a black wooden table and exposed to the sun.

He measured a temperature of 87.5 °C, and in later experiments 110 °C, in the innermost and smallest glass box. DE SAUSSURE did not invent the complete flat-plate solar collector because he did not utilizably withdraw the heat from inside the box. The hot box was further developed by other researchers in the 19th century and used to cook fruit and meat. In 1872, the English engineer C. WILSON distilled saline water with glass-covered vessels, in the hot sun of Las Salinas (Chile), this system produced about 19 000 L of fresh water per day.

The French engineer C. TELLIER (1828 – 1913) used a solar collector for the first time to run a solar thermal pump. The heat carrier ammonia was evaporated in ten flat-plate collectors which were made of iron absorbers placed in glass-covered wooden boxes. In 1904, the Americans H. W. WILLSIE and J. BOYLE continued with the idea of a "collector motor" and developed a solar machine driven by ammonia vapor with an output of 6 hp (4.5 kW).

It is not possible to say who was the inventor of the first solar system for the *heating of water*. In 1891, C. M. KEMP of Baltimore, Maryland applied for a patent for a solar collector for the preparation of hot water. He called the first integrated collector storage system "Climax". It consisted of four cylindrical water containers which were painted black and placed side by side in a glass- covered wooden box. The patent was sold in California in 1895. Despite several further developments, the problem remained that after a sunny day the water in the storage tanks was cold the next morning. This problem was solved only in 1909 when W. J. BAILEY built a solar system with a flat collector and a separate storage tank in a small suburb of Los Angeles. These early systems utilized the thermal buoyancy of the water heated in the collector for the transport of heat. Water was directly passed through the absorber. The absorber consisted of copper tubes with a diameter of 16 mm which were soldered parallel to each other and side by side on a copper plate. The 120 L storage tank was heat insulated with pulverized limestone. After the first frost damages, these single- cycle systems were further developed into two- cycle systems. A mixture of alcohol and water flowed through the collector tubes and indirectly heated the water in the storage tank via an internal heat exchanger. Solar water heaters were sold in larger numbers in California and later in Florida. However, electricity and cheap fossil fuels in the 1930s and 1940s brought a temporary end to this boom. In the 1950s and 1960s, solar technology was further developed in Israel and Australia (e.g., selective absorber layer) and cost-effective thermosiphon systems as well as collector storage systems were sold in large numbers. In Europe, the United States, and Japan, increased attention was paid to the technical utilization of solar energy after the oil crisis of 1974.

For further details about the historical aspects and the pioneers of solar technology, see [10–14].

Figure 5. The solar driven printing press of A. B. MOUCHOT and A. PIFRE (1878)

2.2. Solar Thermal Energy Conversion

The energy released by the sun reaches the Earth in the form of electromagnetic radiation in the wavelength range of ca. 280 to 4960 nm. The spectral distribution approximately corresponds to a black body with a temperature of about 5800 K (Fig. 6). About 90 % of the extraterrestrial radiation is in the range of visible light and near infrared (300 – 1500 nm). The intensity of the radiation at the outer layer of the Earth's atmosphere is on average 1353 W/m^2 (solar constant) with fluctuations of about ± 3 %. The radiation striking the Earth's surface is diminished by absorption, scattering, and reflection in the atmosphere. The maximum values for the radiation measured at sea level are about 1000 W/m^2. The radiation available through an entire year is of importance for technical solar utilization.

The total radiation striking a horizontal surface is called the "annual sum of the global radiation." Figure 7 shows the worldwide distribution of the average annual global radiation, the values being between 800 and 2250 kWh m^{-2} a^{-1} depending on the place and climate. Some typical examples are presented in Table 1. The annual sum can also be characterized by an average power thought to be constant through all the hours of the year. These fictitious values and the annual useful energy attainable for a system efficiency of 35 % (typical value for solar thermal utilization) are given in Table 1.

Table 1. Typical insolation data for various cities

City	Annual sum of global insolation, kWh m^{-2} a^{-1}	Average power, W/m^2	Attainable energy for $\eta = 35\,\%$, kWh m^{-2} a^{-1}
Stockholm	920	105	322
Hamburg	978	110	342

Figure 6. Spectral distribution of the extraterrestrial solar radiation (a) and emission of a black body (b) at 5762 K [15]; (c) Solar radiation at sea level

Global radiation consists of two different parts. One part comes directly from the sun without a change in direction (*direct radiation*). The other part comes from all directions after single or multiple deflections (*diffuse radiation*). The direct radiation can be directly concentrated by reflection and refraction using mirrors and lenses, respectively. The diffuse radiation can be concentrated to only a very limited extent. For this reason, direct radiation is qualitatively more valuable than diffuse radiation. The energy density is increased by the concentration of radiation, which, in turn, results in higher temperatures on absorption. The highest possible degree of concentration is about 46 000 and leads to the maximal temperature of ca. 5800 K produced in a collector by solar radiation.

2.3. Technical Utilization of Solar Energy

The temperature requirements determine the main features of the construction of a collector. The complexity increases with increasing temperature demand. For low temperature applications the *flat plate collector* is used. Simple absorbers without transparent covers are sufficient for temperatures below 30 °C. For temperatures up to 100 °C collectors with one or two transparent covers and a selective absorber surface are used in practice. To provide considerable amounts of energy above 150 °C the flat plate collector must be evacuated. Medium- and high-temperature applications require temperatures higher than 150 °C. Above this limit sufficient efficiencies are only reached by *concentrating collectors* that concentrate the rays of the sun to the absorber. For highly concentrating devices only the direct part of the radiation can be used, for lower degrees of concentration the diffuse radiation can also be utilized in part.

2.3.1. Low-Temperature Applications

The solar collector will be described in detail. Since the supply of solar energy does not coincide with the demand for heat for room heating and water heating, the collected solar energy must be stored. This energy storage will be described in → Heat Storage Media. For solar systems in the low-temperature range, there is, in practice, no alternative to the storage medium water.

Figure 7. Global radiation chart of the world with isopyrene [16]

Figure 8. Basic design of a flat collector and photothermal conversion
a) Covering; b) Thermal insulation; c) Absorber plate

2.3.1.1. Design and Function of Flat Collectors

The basic design and physical transport processes of a flat-plate collector are shown in Figure 8. The most important component is the absorber (c) with a surface that is as completely absorbing for solar radiation as possible. There should be the best possible thermal contact between the absorber plate and a heat-transfer medium (e.g., water, oil, or air) that flows past the plate. The heat generated on absorption is given off to this medium and, thus, withdrawn from the collector (utilizable heat in Fig. 8). To reduce heat losses and improve collector efficiency, the absorber is provided with one or several transparent covers (a) at the front, the sides and back being heat insulated (b). Figure 9 shows various types of liquid- cooled flat collectors which are not described here in detail.

The *absorber* usually consists of a good heat conducting metal (e.g., copper, aluminum). The absorber should have the highest possible absorptance α in the spectrum of solar radiation (α is the ratio of the absorbed radiation to the total incoming radiation). Ideally, this requirement is met by a black body which completely absorbs radiation of all wavelengths λ [$\alpha(\lambda) = 1$]. Real absorber surfaces reach absorption degrees of 0.8 to 0.98. According to the Kirchhoff Law, $\alpha(\lambda) = \varepsilon(\lambda)$, i.e., a good absorber is also a good emitter of radiation (the emittance ε is defined as the ratio of the amount of energy emitted at one wavelength range to the amount that would be emitted by a black body at the same temperature). The spectral distribution of the heat radiation emitted by the absorber depends on its temperature and is defined by the Planck Law. Figure 10 shows that the solar radiation and the heat radiation of an absorber (ca. 80 °C in Fig. 10) cover different spectral ranges. This wavelength difference is made use of by selective absorber layers, which exhibit a high degree of absorption in the solar radiation range and a low degree of emission (same as degree of absorption) in the infrared range. The spectral degree of absorption of black (a) and white paints (c) and of a selective coating (b) is shown in Figure 11. Various selective absorber layers exist which can be classified as interference, semiconductor, and structure filters. In current practice the manufacturing process is shifting gradually from electroplating to sputtering. The values reached for advanced

Figure 9. Types of liquid- cooled flat collectors

layers are 0.95 for the absorptance and simultaneously 0.05 for the emittance.

Figure 10. Normalized spectral intensity distribution for a black body at 5800 K (solar radiation, a) and 350 K (heat radiation of the absorber, b)

The *covering* of flat-plate collectors consists of low-iron glass or transparent plastics in the form of stretched films or capillary structures (honeycombs or transparent heat insulation). The covering should have the highest possible transmission ratio in the spectrum of solar radiation, but it should also be as impermeable as possible to the heat radiation of the absorber. Glass meets these requirements very well, while plastic sheets [e.g., polyethylene, poly(vinyl fluoride)] exhibit optical windows in the range of heat radiation (see Fig. 12).

Figure 11. Spectral course of the degree of absorption of various surfaces
a) Black paint; b) Highly selective coating; c) White radiator paint; d) Mirror

Figure 12. Spectral course of the degree of transmission of various transparent materials
a) Quartz glass; b) Polyethylene film; c) Normal window glass

The transmission of glass panes can be further improved by a treatment of the surface. By etching, the refractive index of the surface layer is reduced to lower the reflectance and increase the transmittance. Structuring of one side of the pane also results in an increased transmittance. Both effects are especially effective at low angles of incidence.

The heat attainable with a collector is described by the *efficiency* η. It is defined as the ratio of utilizable heat energy released by the collector to the incoming radiation energy. Under steady-state conditions, the following efficiency equation can be derived from the collector heat balance:

$$\eta = (\tau_G \alpha_A) - k_m(\theta_{A,m} - \theta_{amb}) / E_{glob,C}$$

where $(\tau_G\ \alpha_A)$ is the product of transmittance and absorptance (the optical collector efficiency, where G = glass and A = absorber); k_m the mean heat transfer coefficient between the absorber plate and the ambient air; $\theta_{A,\,m}$ and θ_{amb} the mean absorber and ambient air temperature, respectively; and $E_{glob,\,C}$ the global radiation in the plane of the collector. k_m increases slightly with temperature.

The collector efficiency is plotted versus the operating parameter $[(\theta_{A,\,m} - \theta_{amb})/E_{glob,\,C}]$. The typical course of the characteristic curve of collector efficiency for a certain incoming radiation, ambient temperature, and wind speed is shown in Figure 13. The *y* axis intercept corresponds to the optical efficiency $(1 - \tau_G\ \alpha_A)$ and the slope of the characteristic curve to the overall heat transfer coefficient (k_m). The curvature of the curve is due to radiative heat losses that increase over-proportionally with temperature (T^4).

Figure 13. Characteristic curve of collector efficiency η
a) Optical losses/$E_{glob,\,C}$; b) Thermal losses/$E_{glob,\,C}$; c) Stagnation point, Ω_{stag}; d) Characteristic efficiency curve; e) Utilizable energy/$E_{glob,\,glob,\,C}$

Figure 14. Typical characteristic curves of efficiency for an absorber (a), flat-plate collector (b, one glass cover, selective surface), and vacuum tubular collector (c)

For practical purposes the equation for the collector efficiency must refer to the mean fluid inlet and outlet temperature. Therefore, the above shown preliminary formula has to be changed, taking into account the heat resistance between the collector fluid and the absorber plate. The final result is given by

$$\eta = F'(\tau_G \alpha_A) - F' k_m(\theta_{C,\,m} - \theta_{amb}) / E_{glob,\,C}$$

where $F' = k_0/k_m$ with k_0 the heat transfer coefficient between the fluid and the ambient air. The typical characteristic curves of efficiency for an absorber, flat-plate collector (with one covering and selective absorber), and a vacuum tubular

collector are shown in Figure 14. Different fields of application (e.g., solar heating of swimming pools or water for domestic use result in varying ranges in the operating parameters. The type of collector to be selected for various applications to achieve the highest possible efficiency factor (same as useful energy) can be approximately determined from Figure 14.

Figure 15. Natural circulation or thermosiphon system with open (A) and closed (B) collector circuits
a) Open expansion tank; b) Collector; c) Double jacket reservoir; d) Reservoir; e) Heat exchanger

2.3.1.2. Systems for Heating Water

A solar water heating system consists of a *collector field* (which can comprise one or, in the case of large systems, many collectors), one or several heat reservoirs, and, depending on the system, heat exchangers, piping, pumps, additional heating, as well as regulation and control equipment. A system functions satisfactorily only when all the components are well suited to each other. Knowledge of the warm water requirements (amount and time profile) and the local weather conditions is required for the dimensioning of a solar system. At present, the following types of system are common:

1) Thermosiphon or natural circulation system (Fig. 15)
2) Integrated collector – storage system (Fig. 16 A)
3) Forced-circulation or "pump" system (Fig. 17)

Figure 16. A) Schematic for the integration of an ICS system; B) Integrated storage – collector with transparent heat insulation
a) Transparent heat insulation; b) Housing; c) Mirror; d) Water reservoir; e) Opaque heat insulation

In the case of a *thermosiphon system*, the heat reservoir must be placed higher than the collector. These plants can be built as open (Fig. 15 A) or closed (Fig. 15 B) systems. The circulation of the heat carrier between collector and reservoir occurs as a result of temperature-based differences in the density of the medium. Since the heat carrier (water or water – glycol mixture) is heated in the collector, it is lighter than that in the reservoir. Circulation starts as soon as the

buoyant pressure is larger than the pressure loss of the entire cycle. Systems of this type can be cheaply built and easily assembled. They require no foreign energy (passive system) and are operated without control elements. Systems based on the natural circulation principle are predominantly used on a small scale (up to 10 m^2 of collector surface area) and are commonly seen on the flat roofs in Mediterranean countries. In Central and Northern Europe the elevated position of the reservoirs poses problems to their integration in the buildings. The Mediterranean arrangement is not accepted, mainly because of aesthetic reasons.

Figure 17. Schematic of a solar water heating system with internal (A) and external (B) heat exchanger in the collector cycle
a) Collector; b) Temperature control; c) Reservoir; d) Heat exchanger

In *integrated collector – storage (ICS) systems*, reservoir and collectors are accommodated in the same housing. The heat losses from the reservoir, especially through the transparent covering, must be kept as low as possible (see Section 2.1, "Climax" made by C. M. Kemp). This is necessary, to withdraw warm water for as long as possible after a sunny day and to protect the reservoir from freezing during cloudy winter days. An example of an ICS system with transparent heat insulation (capillary structure made of polycarbonate) as covering is shown in Figure 16 B.

In *forced- circulation systems*, the heat from the collector is transported to the reservoir by a heat carrier (water or water – glycol mixture for protection against frost damage). A pump is employed to circulate this medium. Instead of a heat exchanger installed in the reservoir (Fig. 17 A), which is usually the case in smaller systems, an external heat exchanger (Fig. 17 B) can also be used, as required in large systems. Forced- circulation systems have the advantage that reservoir and collector can be arranged in any manner. Simple regulation (temperature control) is sufficient to control the system. The circulating pump is switched on when the collector field can supply usable energy to the reservoir, i.e., when the temperature difference between collector and reservoir (at the level of the heat exchanger) exceeds a threshold value which can be set at the control unit. For the climatic conditions and normal warm water consumption (40 L at 50 °C per day and person) in Germany, the following design can be recommended for a solar supported water heating system: collector area of 1.0 to 1.5 m^2 per person and water storage volume of 50 – 80 L per square meter of collector area.

The literature covering collectors and thermal solar systems is extensive. The textbooks by Duffie and Beckman [17] and Kreith and Kreider [18] should be mentioned in particular.

2.3.1.3. Systems for Room Heating

In Central and Northern Europe, relatively large parts of the total final energy consumption (e.g., 30 % in Germany) are used for the heating of buildings. Long-term storage is essential because the seasonal course of the solar energy supply and the consumption of heat for room heating move in opposite directions. Therefore, cost-effective storage systems that store the energy from the summer into the winter are necessary. Increased constructional thermal insulation of buildings (e.g., heating energy index of 40 – 50 $kWh\,m^{-2}\,a^{-1}$) is an economic requirement for the active utilization of solar energy for room heating. Numerous attempts have been

Figure 18. Solar-supported district heating system
a) Collector pipe; b) Heating water distribution grid; c) Heating boiler; d) Warm water distribution grid

made to heat individual houses mainly or even completely with solar energy. However, these normally oversized solar systems can only be recommended if only small contributions to the heat demand are required. Solar-supported district heating systems are technically and economically more suitable. Figure 18 shows the concept in which a larger number of houses are connected to a district heating system. A central long-term heat reservoir (d) is charged to temperatures of up to 95 °C in summer by decentralized collector fields on the roofs of the buildings. In the heating period, the stored heat is transported from the reservoir (in the form of warm water) to the buildings via underground piping. Pilot plants, primarily in Sweden, have shown that this concept functions and the investment costs could be reduced by more than half compared to small solar systems. International research [19] has shown that reasonable designed systems with a seasonal heat storage are able to cover 60 – 80 % of the heat requirements. In this case it is essential that at least 100 to 200 residential units are connected so that a storage volume of several 1000 m^3 becomes necessary. This storage volume is required to reduce the heat losses from the reservoir and to reduce the specific building costs. Figure 19 shows the storage concepts studied in pilot projects which use water, rock, or soil as the storage medium.

Figure 19. Storage concepts for the long-term storage of low-temperature heat
A) Tank; B) Aquifer; C) Ground water pit; D) Horizontal pipe coils, vertical soil sondes; E) Cavern; F) Vertical rock boreholes

Solar heating plants with collector areas up to 8000 m^2 (Marstall, Denmark) and storage volumes for hot water of 100 000 m^3 (rock cavern, Sweden) have been build successfully. Actual

developments concentrate rather on a decrease of cost than on an improvement of technique [20]. Some collectors are equipped with a prefabricated roof module where the wooden roof beams are already integrated in the collector. This collector is installed instead of the conventional roof in new buildings. The additional cost is about 100 Euro per square meter collector. One part of the storage research concentrates on cost-effective constructions that do not depend on special geological conditions such as rock caverns. Problems encountered with well known and cheap materials like ordinary concrete are their high coefficient of vapor diffusion and their sensitivity to temperature stress.

Solar-supported district heating has a very high potential. In Germany more than one third of the total heat demand for heating and hot water supply could be met by solar-supported district heating, even if stringent ecological and economic constraints are taken into consideration. In future cost of seasonal storages and large collector fields will decrease. Taking this into account, the solar potential can be exploited at specific costs ex heat reservoir between 0.03 and 0.10 Euro/kWh [21].

2.3.1.4. Other Low-Temperature Applications

Apart from the heating of water, solar collector systems can, in principle, be used wherever heat for domestic use is required at low temperature ($< 150\,°C$). Despite the current low prices of gas and oil, the solar heating of *open-air swimming pools* is an application that is almost profitable. Inexpensive plastic absorbers (e.g., made of polypropylene or ethylene – propylene – diene rubber) without transparent covering and without heat insulating on the back are used. The pool water flows directly (without a heat exchanger) through the absorber and a monovalent mode of operation (i.e., without a conventional heating system) is possible. The typical system costs are in the range of € 51 (\$ 56) to 102 (\$ 111) per m^2 of absorber and the solar energy yields are between 200 and 250 kWh/m^2 per swimming season.

With the help of air collectors, *warm air* is produced which can be used to dry agricultural or other products. Application of warm air in air heating systems is also possible because of the relatively low temperature level needed. Rock beds or the inner walls, floors, and ceilings (Hypocaustum system) of the building serve as heat storage material. A simple and cost effective system was developed in Canada (Solarwall, Toronto). In this system, the collector consists of a perforated, dark colored facade (ca. 2 % of holes) through which external air is sucked and heated.

Another interesting application is the *thermal desalting of sea water* with simple collector systems. In the simplest case, sea water is heated under a transparent covering by solar radiation and partially evaporated. The water vapor condenses on the inclined covering and runs into a collecting gutter. Large-scale solar distillators were erected rather early. More recent plants are to be found, for instance, on various Greek islands, e.g., Patmos, where the favorable radiation conditions permit the production of 26 000 L of fresh water per day with ca. 8760 m^2 of distillation area.

Highly efficient flat-plate collectors (e.g., vacuum tubular collectors), which achieve temperatures between 100 and 150 °C with efficiencies of 30 – 40 %, are suited to the operation of *continuous absorption refrigeration plants* which use the working fluids lithium bromide – water. Apart from these continuous systems, periodically operating adsorption systems, e.g., based on calcium chloride and ammonia, also exist. The refrigerant (ammonia) is expelled from the fixed-bed absorbent (calcium chloride) with the help of solar energy.

Another application of highly efficient collectors is the *solar thermal pump*. Refrigerant vapor is produced (110 – 130 °C) by using collectors and expanded in a piston motor which drives a water pump. Prototypes (Dornier, Friedrichshafen) are available with a hydraulic pump output of ca. 1 kW and a degree of utilization (daily average) of ca. 3 %.

2.3.2. Medium-Temperature and High-Temperature Applications

2.3.2.1. Concentrating Collectors

Solar radiation must be concentrated to produce heat at high temperature. This concentration is

Figure 20. Concentration degrees of various reflectors and the maximum theoretical absorber temperature as a function of the contact angle [25]
a) Paraboloidal mirror; b) Fresnel lens, $n = 100$; c) Screen mirror, $n = 100$; d) Spherical mirror; e) Paraboloid-type cylinder mirror; f) Conical mirror; g) Circular cylindrical mirror
n = Number of segments

generally achieved with mirrors. The attainable temperature depends on the concentration degree C by which the incoming radiation is intensified (C is the ratio of the aperture area of the optical device to the area of the solar image in the focal plane). The degrees of concentration, in turn, depend on the quality of the optical components and on the type of concentration. For various types of mirrors (reflectors), the theoretical concentration degrees and maximal absorber temperatures as a function of the contact angle are shown in Figure 20. For comparison, the curve of a Fresnel lens is also shown. The maximum theoretical absorber temperature T_A is calculated according to the following equation: $T_A = T_S\ (C/C_{max})^{1/4}$ where $C_{max} = 46\,211$ and $T_S = 5762$ K. In the case of one-dimensional concentration, the radiation is collected at the focal line. To attain higher degrees of concentration, two-dimensional concentration is necessary. In this case, the radiation is collected at the focal point [17], [18], [23], [24]. The degrees of concentration technically obtained today lie between 40 and 80 in the case of linear concentrators (e.g., parabolic troughs). Values of up to 2500 are achieved with concentrators that are two-dimensionally effective (e.g., paraboloidal mirrors). Tower power plants (see Section 2.3.2.2) with biaxial tracking heliostats have been built with $C = 200$ to 700.

The schematic design of a *concentrating collector* is shown in Figure 21. The collector consists of two parts, the reflector that focuses the radiation and the absorber. The two parts can be firmly joined together and can follow the sun together or they can be separated, as in the case of tower power plants (see Section 2.3.2.2). The incident rays must always be kept focused to the absorber. Therefore, in contrast to flat-plate collectors, tracking is required in the case of concentrating collectors. *Biaxial tracking* is necessary for paraboloidal mirrors. For parabolic troughs that are mounted horizontally *monoaxial tracking* is sufficient to obtain good results. Two alignments of the trough are possible. For locations near the equator the north-south direc-

tion and for higher latitudes the east-west alignment give the highest energy yields.

Figure 21. Basic design of a concentrating collector
a) Absorber; b) Tracking device; c) Paraboloid reflector D = Aperture, m; ϕ_c = Contact angle, °; f = Focal length; d = Absorber diameter

The absorber in the focal plane of a concentrating collector should absorb the solar radiation, convert it to heat as completely as possible, and transfer it to the fluid heat carrier. According to the constructional design, a distinction is made between *open receivers* (Fig. 22 A), with and without transparent covering (e.g., an evacuated glass tube around cylindrical absorber tubes in the case of parabolic trough collectors) and *cavity receivers* (Fig. 22 B) which have only a small opening for radiation. Another concept uses so-called "volumetric absorbers" made of highly porous materials. The concentrated solar radiation is absorbed within the structure ("in the volume") and the heat is transferred to the medium that is passed through the absorber.

Figure 22. Types of absorbers for solar tower power plants
A) Open absorber; B) Hollow-space absorber; a) Absorber tubes; b) Aperture; c) Heat exchange tubes

In a concentrating collector, the most important losses include:

1) Incomplete reflection of the mirror
2) Surface faults on the reflector
3) Orientation errors caused in tracking
4) Reflection at the absorber
5) Heat losses (radiation, convection) at the absorber

2.3.2.2. Solar Thermal Power Plants

The indirect conversion of radiation energy to electricity via the production of thermal and mechanical energy occurs in solar power plants. The thermodynamic cycle corresponds to that of a conventional steam or gas turbine power plant. A distinction is made between farm and tower plants, depending on the type of collector employed. In a *farm plant*, each collector has its own absorber. It uses either line focusing parabolic troughs or point focusing parabolic dishes. The parabolic troughs are connected to a central machine unit (Rankine cycle) via a piping system that is usually operated with the heat transfer medium thermooil at a maximum temperature of 400 °C (Fig. 23). For the parabolic trough no heat transfer is necessary if the absorbed energy is directly transformed to electricity in a Stirling engine that is mounted near the focus.

Solar tower plants possess many biaxial mirrors (heliostats) that follow the sun. The mirrors reflect the solar radiation onto a common central absorber (receiver) which is on top of a tower (Fig. 24). A heat transfer medium (steam, air, molten salt) transports the solar heat to the machine unit, usually a Rankine cycle.

Central receiver plants using closed (pressurized) volumetric receivers can drive gas turbines (Brayton cycle) or combined cycle power plants. The high conversion efficiency of combined cycles will allow for solar-to-electricity efficiencies of over 25 %. This technology is presently in the R&D phase.

Since 1973, about 35 solar farm power plants with ca. 1 885 000 m^2 of mirror area and an electrical output of ca. 300 MW have been built. The farm and tower plants (500 kW electrical output each) in Almeria, Spain studied in the course of an international research and development collaboration are shown in Figure 25. Between 1985 and 1989, a series of large-scale farm plants with an electrical output of 30 and 80 MW

Figure 23. Schematic of a solar plant based on the farm concept
a) Collector field (parabolic troughs); b) Field pump; c) Reservoir; d) Reservoir pump; e) Evaporator; f) Condenser; g) Screw expander; h) Gear; i) Generator

were put into operation in California's Mojave desert. The net annual efficiency factors of these plants are around 9 % and the investment costs between \$ 3500 and 4000 per kW_e. Presently projected plants of this type will have annual conversion efficiencies of 13 – 15 % and a cost of \$ 2000 – 3000 kW_e. The combination of parabolic troughs and combined cycles can lead to investment costs of less than \$ 1000 kW_e. Up to now only six tower power plants have been built with a total output of about 16 MW. At present, the largest power plant based on the tower principle (Solar Two) with an electrical output of 10 MW is also to be found in the Californian desert near the city of Barstow. The net annual efficiency factor is ca. 6 % and the specific investment costs of this pilot plant are ca. \$ 14 000 per kW_e. Presently projected plants of this type will have an annual conversion efficiency of 13 – 15 % and costs of \$ 3500 – 4500/kW.

2.3.2.3. Solar Process Heat

The temperature distribution for industrial process heat in Germany is shown in Figure 26. It is obvious that there are two foci for the heat requirements, in the temperature ranges 100 – 400 °C and 1200 – 1500 °C. Temperatures up to 400 °C can be covered by parabolic trough collectors. Tower receivers cover up to 1200 °C, temperatures of 3000 °C are technically possible with biaxial tracked paraboloidal mirrors. The applications range from simple solar cookers for developing countries (to reduce the consumption of firewood) to solar melting furnaces. The largest solar furnace having a thermal output of 1000 kW was built in 1970 in Odeillo in the French Pyrenees (see Fig. 27). The maximal attainable temperature is almost 4000 °C.

3. Passive Utilization of Solar Energy

3.1. Introduction

In recent times, highly developed air-conditioning technology has increasingly been

Figure 25. Pilot power plants in Almeria (Spain) based on the farm and tower concept

Figure 26. Typical temperature distribution for process heat in Germany (1982) [24]
tce = tons of coal equivalent

used to provide thermal comfort, without asking whether the building substance has been constructed in accordance with the climatic conditions. In contrast, it is more meaningful to think about the traditional methods of construction which arose through optimal adaptation to the climate of a particular region. Buildings of this type, which can, of course, be constructed by using modern technology and materials, have very low energy requirements. They conserve resources of fossil fuels, contribute to environmental protection, and are also more economical.

The most important measures taken to minimize energy losses in buildings and the possibilities for the passive utilization of solar energy are described in this chapter. The radiation gains in solar buildings of the type shown in Figure 28 can be substantial. This house is characterized primarily by a pleasant climate and low heat re-

quirements. In other cases, especially in commercial buildings, a reduction in electrical lighting by the use of daylight and a decrease in ventilation or cooling costs can also be important. Passive solar measures are most efficient if they are considered during the planning stage of the building. However, even in the case of existing buildings, the heat balance can be substantially improved through renovations. An example of a successful renovation of a multifamily dwelling is shown in Figure 29. The facade of this house was changed into a solar facade.

Figure 27. Schematic of the radiation path in the solar furnace in Odeillo
a) Movable plane mirror; b) Focus, 18.40 m; c) Concave mirror

Figure 28. South view of the ISFH experimental building in Emmerthal, Germany
Right: solar house with conservatory and transparent insulated walls. Left: reference building

Passive utilization of solar energy refers to the direct transformation of radiation energy into heat by the structure of the building, i.e., by means of transparent and storage building components. In comparison with active measures (e.g., heating of water for domestic use by using collectors, see Chap. 2), none or very little auxiliary energy is required for additional systems. The principles involved in the passive utilization of solar energy are: collection of radiation energy, storage of the collected energy, and utilization of the stored energy in a controlled manner. Windows, sun spaces, solar walls, and air collectors represent the most important components. Several aspects have to be considered before selecting passive components. These include location factors, shape of the building, orientation, room arrangement, ventilation, and insulation.

Figure 29. A renovated multifamily dwelling building in Freiburg, Germany
The building has been provided with transparent insulation (Project leader: Fraunhofer Institute of Solar Energy Systems, Freiburg.)

3.2. Building Design

3.2.1. Site Analysis

An energy-conscious building design requires an exact analysis of the climatic factors and the conditions of the site. The most important climatic factors are solar radiation, temperature, humidity, wind, and precipitation. Average values determined over longer periods of time can be obtained from the weather service or from the relevant literature. The annual average temperature and solar radiation measured in Hamlin (Germany) are shown in Figure 30. However, the architect must also take the local conditions (microclimate) into account. In the heating period, shading of the building can considerably reduce the utilizable solar radiation. In summer, shading can help to protect the building from overheating. The most favorable location for the utilization of solar energy is an incline facing the south, although the free selection of a building site is seldom possible. Periods of shade (ob-

Figure 30. Average monthly temperature and solar radiation (global, horizontal) in Hamlin, Germany

struction profiles) can be determined with a solar chart (Fig. 31). The topology of the site, the vegetation, and the buildings in the neighborhood have a strong influence on the speed and direction of the wind. Wind enhances transmission losses by cooling the building envelope and increases infiltration through leaks. For this reason, wind barriers reduce the heat requirement during the heating period.

3.2.2. Design

A compact building has a smaller outer surface area and fewer heat losses than a strongly structured building with the same volume. When designing the building, this must be taken into account by providing the smallest possible surface-to-volume ratio.

Passive solar buildings should be built as far as possible in the east – west direction. They should have large apertures toward the south. Windows in the south facade achieve the highest solar gains so that their annual average total heat balance is positive.

Rooms that are not continuously lived in and are not heated can be located as buffer rooms in the temperature gradient between the inside and the outside (zoning). Staircases, garages, storerooms, and porches can be considered for this purpose. Buffer rooms exert their thermal effects on all sides of the house.

Furthermore, efforts should be made to provide effective daylighting and uniform heating by means of natural convection and ventilation. A cross section of the solar houses shown in Figure 28 is presented in Figure 32. In these houses, the principles of zoning and the creation of buffer zones have been consistently applied. The location on a slope facing the south was exploited by a split-level design.

A reduction of the outer surface area can also be achieved by combinations to form larger living units. In comparison with detached one-family houses, the room-heat requirements of one unit in a residential building with several stories can be reduced by 50 %.

3.2.3. Heat Conservation

The utilization of solar energy in buildings only makes sense when basic measures of heat conservation have been taken. The heat losses in a building are made up of transmission losses through the building envelope and infiltration losses. Therefore, good insulation of the outer envelope represents the highest energy saving potential; attics and floors above unheated cellars are to be included in the heat conservation concept. The thermal transmittance (U value) of the walls should be less than $0.3\,\mathrm{W\,m^{-2}\,K^{-1}}$. It is advantageous to equip windows with heat-conserving glass.

The exchange of air during the heating period means a continuous removal of heated air and, consequently, energy. Unintentional ventilation through badly fitting windows, doors, and cracks, etc., must be avoided. The necessary supply of fresh air can be controlled more efficiently by means of a ventilation system than by opening the windows. The energy consumption can be reduced still further by means of a heat re-

Figure 31. Solar chart for a location of 52° north with obstruction profile. The sun path lines apply to the 21st of each month

covery system. Air exchange rates of $0.5\,h^{-1}$ to $1\,h^{-1}$ are sufficient in most cases.

a) Conservatory; b) Living room; c) Kitchen; d) Storage room; e) Porch

3.3. Elements of Passive Utilization

3.3.1. Collection

Windows. With exposure of windows to solar radiation, considerable heat gains can be attained. As basic elements of buildings, windows represent the simplest system for the passive utilization of solar energy.

Incident solar radiation can pass through glass almost unimpaired (Fig. 33). On striking walls, ceilings, floors, and items of furniture, the radiation energy is converted to heat (direct utilization). The heat capacities of these items of construction should be large to prevent an excessive increase in temperature. The heated areas emit part of the absorbed energy. Since the emitted radiation is in the infrared region, it cannot get through to the outside, because infrared radiation cannot penetrate glass. Therefore, the heat remains in the room (greenhouse effect). The absorbed energy is distributed in the building by means of air convection.

Figure 33. Radiation balance of a window pane

The solar gains from vertical windows depend on the orientation, the largest gains being achieved from windows facing the south. They always have a positive heat balance, i.e., the solar gains are on an average larger than the heat losses. Vertical glass surfaces prove to be especially favorable. The intensive summer radiation comes in at a steep angle and the irradiance is decreased. This, in turn, reduces the danger of overheating in summer. The desired winter sun-

light enters at a flatter angle resulting in a higher irradiance of the window area. The dimensions of the windows depend on the radiation supply of the site, the heat requirements of the building, and on the size of its storage mass.

Windows should be equipped with heat-conserving double glazing. As a result of a special coating with a low infrared emittance and an argon filling, this glazing has losses that are only about half as high as those of simple double glazing. The U value of heat-conserving glazing is $1.3\,\mathrm{W\,m^{-2}\,K^{-1}}$. Shutters, curtains, etc., provide additional insulation during the night.

Sun Spaces. An attached sun space or conservatory (Fig. 34) fulfills many functions: it heats up when insolated, it can give off excess heat to adjoining rooms, and it forms a buffer room against fluctuations in the outside temperature. It can also be an attractive living room in the warmer months.

Figure 34. South view of an achitectural model with distinct sun spaces

The prerequisite for efficient functioning is that the conservatory remains unheated. If plants are grown in this conservatory, the supply of heat must be limited to frost protection. The connecting wall and the floor serve as thermal stores and heat-conserving glazing increases the utilization potential. To guarantee its function as a buffer room, the connecting wall should not be permanently kept open. In the case of sufficient insolation, the fresh air for the main house can be preheated in the conservatory. To exclude overheating, shading elements and an adequate ventilation of the conservatory are required.

Solar Walls. In the simplest case, a solar wall is a glazed outer wall which is painted black and as far as possible faces the south (Fig. 35). It should consist of a material that is a good thermal conductor with a high heat-storing capacity, e.g., concrete or solid stone masonry. The single or double glazing is attached about 10 cm in front of the wall. It reduces heat losses to the outside air. Solar radiation is absorbed on the outer surface of the wall, the heat is transferred to the inner surface of the wall by conduction, and it is then emitted into the room by means of radiation and convection. Roofs and walls that do not have transparent insulation conduct inwards only a negligibly small part of the heat generated by the absorbed radiation.

Figure 35. Sketch of a solar wall
a) Glass cover; b) Storage wall; c) Ventilation flaps

The insulating effect of the glass pane and, consequently, the effectiveness of the solar wall can be substantially increased by the additional provision of transparent insulation materials [27], [28] made of polycarbonate or polyacrylate (Fig. 36 B). The insulating layer consists of tubes or honeycombs with a diameter of ca. 2 mm to 2 cm arranged vertically to the front pane; the layer thickness is up to 10 cm. Solar walls should also be provided with shading facilities.

The variations in temperature occurring on the outside of the solar wall are greatly suppressed inside. The peak temperature appears at

the inner surface with a delay of several hours (Fig. 37). It is also possible to start air circulation by opening ventilation flaps which allows an immediate heat supply to the living rooms.

Figure 36. Structure and energy flow diagram of an opaque insulated wall (A), compared with a transparent insulated wall (B)
a) Wall; b) Insulation; c) Weather protection; d) Absorbent paint; e) Transparent insulation; f) Glass pane

Air Collectors. In air collectors, the energy of the solar radiation is directly converted to thermal energy of the air; no additional storage masses are required. The collection of radiation energy occurs at suitable points, e.g., in the roof (Fig. 38). The lamella improve the heat transfer between the absorber and the air. The heated air is transported through ducts to rooms which do not receive sufficient radiation. A distinction is made between operation by circulating air and *fresh air* operation. Air circulation can be achieved by natural convection, if the collector is suitably arranged, or with the help of blowers. Air collectors require a highly transparent covering with good thermal properties.

Figure 37. Daily pattern of the surface temperature of a transparent insulated solar wall and the air temperature in the adjoining unheated room. The solar radiation on the vertical was 5.6 kWh m^{-2} d^{-1}, the average outside air temperature was 2.9 °C
a) Outer surface temperature; b) Inner surface temperature; c) Room air temperature

Figure 38. Air collector in the roof

3.3.2. Storage and Distribution

The utilization of solar energy must be adjusted to a very irregular energy supply. If the energy of the incoming radiation is to be utilized over and above the immediate requirements, it must be stored. Fluctuations in the room temperature are suppressed and delayed by the storage of heat.

The surface of storage masses that are directly irradiated by the sun heat up and conduct a part of the energy inwards (*primary storage*). A storage mass can also undergo convective loading (*secondary storage*) if heated air passes its surface. Heat transfer then continues until the surface temperature of the building component is the same as the air temperature.

Apart from the utilization of construction elements already present in the house as thermal stores, additional elements such as *water tanks* can be used. Heat stores outside the house have also been tested. The efficiency of a store depends on a series of parameters. The most important are its heat capacity, the velocity of heat penetration, and the size of the exposed surface.

Careful planning is required to achieve distribution of the collected energy through natural convection currents (Fig. 39). In many cases, mechanical ventilation systems cannot be avoided. Moreover, they have the advantage that the consumption of stored heat can be controlled and thus be restricted to times of need.

Figure 39. Schematic representation of the passive utilization of solar energy: collection, storage, and distribution
a) Solar radiation; b) Reflection; c) Charge and discharge; d) Infrared radiation; e) Convection; f) Transmission losses; g) Infiltration losses

3.3.3. Shading and Cooling

Efficient solar buildings always hold the danger of overheating in summer. In fact, in hot climatic regions, the avoidance of solar-energy input into the house represents the central aspect of the building design. If large apertures are to be used for solar heating as and when necessary, shading equipment must be provided. Apart from fixed eaves, movable elements such as blinds, shades, awnings, or folding shutters have proved useful. External shading equipment is more effective than internal equipment.

Figure 40. Section of a prismatic pane (h) for seasonal shading of buildings with refracting surfaces (a, b) and the course of two principal rays. Incident sun rays (c, d) are directed to the rear surface (e) in such as way that they are either transmitted (f) or reflected. Reflection occurs when the angle of incidence is higher than the critical angle of total reflection.

Great importance is attached to the use of windows with thermochromic or electrochromic coatings in the future [29]. They can be employed to realize an intelligent building envelope, which automatically controls its optical transmission properties in accordance with the energy requirements. On reaching a threshold temperature, *thermochromic coatings* switch from transparent to diffusely scattering. On the other hand, *electrochromic coatings* switch from permeable to absorbing on application of an electrical field. A very effective seasonal shading that is responsive to the sun's position can be realized with prismatic panes (Fig. 40). These

panes are suitable for window or facade elements, preferably in applications where no clear view is required, and especially in front of transparently insulated solar walls. The direct radiation received on a vertical south-facing facade is reduced to 10 % on clear summer days, while 90 % is transmitted on clear winter days [34].

Apart from shading, adequate ventilation must be provided. In particular, airing at night can contribute to the cooling of storage masses in the house. Mechanical ventilation systems can also make use of the coolness of the ground by leading the fresh air into the building through pipes laid in the ground.

3.3.4. Daylight

Solar design implies avoidance of artificial lighting whenever daylight is possible [30]. However, it is not only the saving of electricity that is important. Daylight increases visual comfort, enhances natural colors, and increases contrasts. Moreover, direct light permits contact with the outside world.

Suitable reflectors, e.g., in skylights, are employed for homogeneous lighting, even in internal rooms.

3.4. Performance of a Solar House

Information about the performance of solar houses is available in a large number of test reports on controlled passive solar systems [31]. Architects and civil engineers can refer to these reports when working out a concept for a construction project, selecting and dimensioning solar components, or for an estimation of the economics. Figure 41 shows the monthly consumption of heating energy and the solar savings of the ISFH solar house for the heating period of 1992/1993.

Highly developed computer programs, which allow the simulation of buildings to be planned, are available commercially. Weather data for all possible climatic regions are supplied with these programs. The simulations reveal room temperature patterns and heating or cooling requirements. Plans can be optimized stepwise by using test runs with varying parameters. A review of the programs available can be found in [32], [33].

4. Photovoltaic Systems

Since the development of the first solar cell in 1954 [35], annual photovoltaic (PV) module production in 1992 had increased to ca. 60 MW (peak) [36]. The main fields of application are:

1) The "power sector", i.e., stand-alone systems for lighting, communication, water pumping, village electrification in developing countries, etc., as well as grid- connected PV systems of the kW to the multi-MW range.
2) The "consumer electronics sector", i.e., small-scale PV systems powering, e.g., pocket calculators and wrist watches. The market share of this sector is ca. 20 %.

These figures indicate that photovoltaics have established themselves as an "additional" energy source with good prospects for the future, even if limited to the present fields of application. Up to now PV systems have not been able to achieve the status of a real "alternative" energy source. As before, the high cost prevents photovoltaics from successfully entering the field of large grid-connected central station power plants.

Modularity, the possibility to construct PV energy supplies from the mW to the multi-MW size, is the likely specific property of PV that has enabled its relatively wide distribution.

Tracking and *concentration* have been increasingly discussed and investigated, because:

1) Prices of PV modules have not decreased to values predicted 10 years ago
2) Concentrator solar cells are now available on the market

According to P. Maycock [37], concentrating PV modules show good cost perspectives (between conventional and thin film cells) up to the year 2010.

4.1. Principle of Operation, PV Materials, and State-of-the-Art Solar Cells

Solar cells make use of the photovoltaic effect in semiconductor $p-n$ junctions or related structures. In principle, the energy of light quanta is

Figure 41. Monthly heating energy requirement and solar savings of the ISFH solar house

transferred to the electronic subsystem of the semiconductor (and not to the lattice!) and can be subtracted from the device directly as electrical energy. For details of the operation principle and of the state-of-the-art, see → Photovoltaic Cells.

Figure 42. Photovoltaic systems
A) Simple d.c.-system; B) Sophisticated d.c.-system; C) System with a.c.-load or grid- connected system

Concerning materials for photovoltaics, *crystalline silicon* (c-Si) is still the most widely used in the field. In the laboratory efficiencies as high as 24 % have been obtained.

The most attractive alternatives are materials that enable the production of thin-film solar cells. Among these, *amorphous silicon* (a-Si) is playing the dominant role, especially in the consumer electronics sector. Efficiency values obtained in the laboratory are 13 – 14 %, however, with a-Si, modules, they are degrading during operation to values well below 10 %. Due to these stability problems a-Si has not been used in the power sector up to now.

Other promising materials are $CuInSe_2$ (*CI S*), *CdTe*, and related compounds. Efficiencies of 15 % have been achieved [38], [39], and stability problems are unknown, however, large-scale industrial production has not yet started.

Further alternatives are GaAs and related *III – V- compounds*. Efficiencies close to 30 % have been achieved with one-sun illumination and 34 % with concentrated sunlight [40], however, due to the high production cost the application of III – V compounds might be limited to concentrating PV systems.

4.2. General Structure of PV Systems

Structures of photovoltaic systems are shown in Figure 42, starting in A with the simplest system, a d.c. -load coupled directly to the PV generator. A more sophisticated system, as shown in Figure 42 B, includes maximum power point (MPP) tracking that provides impedance matching between the dynamic resistance of the solar generator and the load, and a d.c. – d.c. converter

for voltage adaption. Storage facilities can also be optionally included in the system.

The connection of PV generators to a.c. loads or to the public grid requires a power conditioning unit (PCU) consisting of at least a d.c. – a.c. inverter (see Fig. 42 C). In most cases the inverter also includes the function of an MPP tracker; optional back-up and storage units may be added to the system.

Figure 43. Present constructions of flat-plate modules with A) Discrete; B) Thin-film solar cells
a) Frame; b) Front cover; c) Solar cells; d) Embedding material; e) Back cover; f) Gasket

4.3. Photovoltaic Generators

The smallest PV unit which is easy to handle for the user, is a *module*. A number of modules mechanically assembled to a larger unit and electrically interconnected is, according to IEC standards, named *array*. Large generators may consist of a number of arrays or even *array fields*.

4.3.1. Module Technology and Specifications

The construction elements of modules with discrete or thin-film solar cells are shown in Figure 43. The requirements for the front cover (b) – low reflectance, good optical transmission, chemical durability, abrasion resistance, mechanical stability, and simple processing – are fulfilled by low-iron glass with a typical thickness of 2 – 3 mm, that is tempered or chemically hardened. The frame of a module (a) is formed by aluminum or stainless steel profiles.

Two materials have proven to be suitable for embedding the solar cells (d): poly(vinyl butyral) (PVB) and ethylene – vinyl acetate copolymer (EVA). Both are thermoplastics. EVA has a better light transmission than PVB, but effort is required to obtain good adhesion to glass and solar cells.

The back cover (e) of a photovoltaic module consists either of a glass plate or a back sheet system of Tedlar [poly(vinyl chloride)] – aluminum foil – Tedlar and protects the solar cells from environmental influences.

Two additional design objectives exist:

1) To keep the operating temperature of the solar cells as low as possible
2) To choose optimal electrical interconnection schemes

The importance of the first goal results from the fact that the efficiency of solar cells decreases with increasing temperature. Since module temperature increases with irradiance, the module efficiency in practice decreases with increasing irradiance [41]. This has also been revealed by outdoor tests carried out at ZSW, Baden-Württemberg (see Fig. 44 and [41]).

The second objective covers aspects such as shading losses and "hot spots". These occur when, e.g., in a string of series- connected cells one cell is partially shaded or damaged. Without protection measures the shaded cell becomes reverse biased and acts as a load. The dissipated power in this load heats the cell. This so- called hot spot can irreversibly damage a module.

Cell damage can be avoided and the output power may be increased if a shunt or bypass diode is connected across the shaded cell. A similar effect occurs when cells or modules are connected in parallel. In this case, a reduction of power losses can be achieved by a blocking diode connected in parallel to the shaded cell.

For designing and modeling of PV plants, correct and reliable data on the performance

Figure 44. Temperature dependence of efficiency of PV modules on illumination according to outdoor tests at ZSW (Centre for Solar Energy and Hydrogen Research), Baden-Württemberg

of PV modules are required. Furthermore, fair competition among module producers should be ensured. Consequently, there was a strong need for standardization of the efficiency rating of PV modules. At present, the nameplate rating of PV modules has to be performed under test conditions according to the IEC Test-Specification 503:

1) Irradiance 1000 W/m^2
2) AM 1.5 spectrum according to IEC Document 904
3) Solar cell temperature 25 ± 1 °C

These Standard Test Conditions (STC) are internationally accepted, together with the agreement that the nameplate rating must be within ± 10 % of the STC value.

Since the energy generation of PV modules depends on the site-specific meteorological conditions, computer models have been developed for the simulation of PV power production from meteorological data and PV module measurements and ratings (see, [42], [43]).

4.3.2. Tracking and Concentration

Methods of PV *array tracking* including fixed-tilted orientation are depicted in Figure 45. The selection of a method depends, among other aspects, on the geographical latitude of the site: horizontal N – S-axis tracking (D) is suitable for sites near the equator, vertical axis (B) suits for high geographical latitudes, and polar axis (inclined axis) (C) and two-axes tracking (A) can be applied everywhere.

Figure 45. Methods of PV array orientation
A) Two-axes tracking; B) Vertical-axis tracking; C) Polar axis tracking; D) Horizontal-axis tracking; E) Fixed, tilted

Using average monthly readings of global and diffuse irradiation and appropriate irradiance models which are calculated on an hourly basis, the annual irradiance gain by tracking has been calculated for Weihenstephan (near Munich, Germany) [43]:

Two-axes tracking:	+ 33 %
Inclined-axis tracking (40°):	+ 30 %
Vertical-axis tracking (53 °):	+ 30 %
Elevation tracking:	+ 6 %

The degrees in parentheses indicate the inclination angle of tracking axis (40°) and of modules (53°) on the tracker. Elevation tracking – not shown in Figure 45 – is a tracking mode following only the elevation angle of the sun (e.g., tracking around the east – west-axis).

Concentrated photovoltaics are possible with various technologies. An overview is given below

Point-Focus Devices:
- Fresnel lens
- Parabolic dish

Linear-Focus Devices:
- Linear Fresnel lens
- Parabolic trough

Nontracking Devices:
- Compound parabolic concentrator (CPC)
- Other nonimaging devices

Point- and linear-focus Fresnel concentrators have been mostly used. Typical concentration ratios are ca. 25, with the tendency to higher ratios. A schematic of a conventional concentrator module package is shown in Figure 46. In Figure 47 linear- and point-focus concentrator modules on a test facility are shown. To achieve high concentration ratios, the cusp in Figure 46 is improved to a "second concentrator" mounted directly to the surface of the solar cell.

Figure 46. Concentrator module package with Fresnel lenses
a) Reflux- cooler panel; b) 24 inch (61 cm) square Fresnel lens; c) Cell mount; d) Cusp; e) Shield; f) Fiber-glass housing

A second strategy is *soft concentration* by, e.g., mirrors mounted at the side of the PV modules. This technology utilized ordinary "one-sun modules" (standard-type modules designed for application without concentration) in connection with simple plane mirrors ("V-trough"). The main idea behind this concept is that both the modules and the plane mirrors are available as mass products. Figure 48 shows the world's largest PV plant at Carrisa Plains, United States, using this technology. At the Carrisa Plains site, a "browning" (discoloration) of the encapsulant in the PV modules occurred due to the high operating temperature of the modules.

Figure 47. Concentrator modules with linear- and point-focus Fresnel lenses on a test facility in the United States

Figure 48. 6 MW (peak) PV power plant at Carrisa Plains, United States, using V-trough concentrator technology

4.4. Power Conditioning Systems

The operational units of a power conditioning system are shown in Figure 42. The design characteristics of PV systems are:

1) Systems with d.c.- load
   a) d.c. – d.c. Converter with fixed input voltage (simple, inexpensive)
   b) Controlled d.c. – d.c. converter providing also MPP tracking

2) Systems with a.c.-load or grid-connected systems
   a) d.c. – a.c. Inverter with constant d.c.-voltage input
   b) d.c. – a.c. Inverter also performing MPP tracking

d.c. – a.c. Inverters can be designed to operate:

1) Externally commutated (for grid connection), or
2) Self-commutated (for stand-alone applications, but also usable for grid connection)

Technical details of these power conditioning components are given in [44]. The central component is the d.c. – a.c. inverter. The most common types are:

1) *Square wave generator* (thyristor bridge inverter). Produces high harmonic distortion of a.c.-output, filter required; however, simple, robust, suited for high power applications.
2) *Pulse-width-modulated (PWM) inverter*
   a) with low-frequency transformer
   b) with high-frequency transformer

   Properties: line- and self-commutated versions, low harmonic distortions, higher cost, applicable only to lower power ranges (< 50 kW). However, due to progress in IGBTs (Isolated Gate Bipolar Transistors), PWM inverters can now be realized up to the power range 1 MW.

Inverter efficiencies are close to 90 % at nominal power. The main problems are their lower efficiencies at partial load and the losses occurring during standby, start-up, and shutdown.

4.5. Storage

For energy storage predominantly lead – acid and nickel – cadmium batteries are used because of their reliability, availability, and flexible sizing. The main disadvantages are their high cost, low-energy-density, and the need for careful treatment. The number of possible cycles during their lifetime decreases drastically with the depth of discharge. Advanced electrochemical cells could improve energy density, self discharge rate, and cycle life. Two promising systems are $Na - \beta\text{-}Al_2O_3 - S$ and $Zn - ZnBr_2 - Br_2$.

Figure 49. 4.5 kW (peak) PV system at "Unterkrummenhof", Black Forest, Germany

4.6. Stand-Alone PV Systems

For many applications, especially in remote places far away from the public grid, PV is an economic power source. In the dry, sunny regions of the world there is a tremendous need for water pumping (drinking water and irrigation), village electrification, and other applications which could be met by photovoltaics more economically than by other methods.

Even in industrialized countries a large market for photovoltaics exists to meet electricity needs in remote areas; for example, the powering of buoys, emergency telephones at highways, or weekend houses. This market is even considered to the several megawatts per year in Europe. Figure 49 shows the PV system of the "Unterkrummenhof", a hiker's inn in the Black Forest in Germany. The 4.5 kW(peak) PV system, equipped with storage battery and diesel back-up, has been designed by the Fraunhofer Institute for Solar Energy Systems (ISE), Freiburg.

4.7. Grid-Connected PV Systems

The present situation can be characterized as follows:

1) Large grid-connected PV power plants were installed in the United States from the late 1970s onward (see Fig. 48).

2) Numerous systems were erected in Europe in the early 1980s, sponsored by the Commission of European Communities. Meanwhile, local authorities and utilities are financing and operating PV power plants. Figure 50 shows the PV power station at the Lake of Neurath, erected by RWE Energie AG, Essen, Germany.
3) Even though energy from PV is far from being competitive with energy supplied from the public grid, the interest in installing grid-connected PV in the private sector has increased, stimulated in several countries by financial support from the government, e.g., by the "1000-Roofs-PV-Programme" in Germany.

Figure 50. 360 kW(peak) PV power plant of RWE Energy AG at Lake of Neurath/Grevenbroich, Germany (photograph RWE)

4.8. Design Considerations and Modeling

The design of a PV plant starts with selection of site and the type of system. The site properties influence whether fixed-tilted, flat-plate tracking, or concentrating systems will be chosen. A critical plant design parameter is the *voltage level:* a high nominal voltage keeps ohmic losses low, but increases cost for high-voltage d.c. hardware and requires additional safety measures. Because of decreasing inverter efficiency at partial loads it may be useful to split the d.c. – a.c. inverter into several units with lower nominal power.

About 15 – 20 design models for PV systems have been developed and are being refined. A summary is given in [45]. Representative examples are:

1) *SOMES* (for stand-alone systems including PV, wind turbines, battery storage, and back-up energy source) [46]
2) *PVFORM* (for stand-alone and grid-connected systems; high accuracy claimed) [47]
3) *ASHLING* (for all types of systems; extensively validated on component level) [48]

4.9. Operational Experience

Detailed performance evaluations of grid-connected PV plants installed in the United States and in Europe have been reported, see [49–51]. They are summarized in the following:

4.9.1. PV Module Performance

Crystalline Si modules are well-developed industrial products of high reliability and low degradation of efficiency (<1 % per year). Lifetimes of 20 – 30 y can be assumed, however, confirmation of this is still required.

Amorphous Si modules have not yet proven their suitability for large-scale power production.

The *practical field efficiencies* of crystalline Si PV modules are 10 – 20 % lower than manufacturer's nameplate d.c. power ratings.

4.9.2. PV System Efficiency, Annual Energy Output

The total *balance of systems* (BOS; all components except PV modules), electrical losses caused by module and array mismatch, wiring, shadowing, dirt, inverter, and control system, are in the range of 15 %.

The *annual energy output* of the entire PV plant is ca. 70 – 80 % of the product of annual insolation and manufacturer's rated module efficiency for crystalline Si-based systems.

Small grid- connected systems can energetically operate as efficiently as large centralized systems.

Using *tracking of arrays*, the annual energy output can be increased by up to 30 %.

4.10. Economic Aspects, Market, Energy Payback, Prospects

Stand-alone and grid-connected systems must be clearly distinguished when discussing the economics of PV. The multifunctional use of PV modules (PV roofs, PV facades, etc.) must also be considered.

4.10.1. Stand-Alone PV Systems

As mentioned before, the field of application of stand-alone PV systems is huge in both developing and industrialized countries. The world market is expected to be between 100 and 400 MW by the year 2000 and might be only limited by the financial capabilities in Third World countries. Energy payback, in this context, must not necessarily be considered a decisive problem. The primary concern is often the availability of energy.

4.10.2. Grid-Connected PV Systems

The economics of PV power plants are dominated by the installation cost; there is no fuel consumption, and maintenance cost can be assumed to be low as compared to investment cost.

The prices of PV modules, in contrast to predictions, have not continuously decreased, they even increased from values ca. $ 4/W(peak) in the late 1980s to ca. $ 5 – $ 7/W (peak) in 1992. The total cost of PV systems in 1991/1992 was in the range of $ 10/W(peak). Characteristic figures are given in Figure 51.

The "annuity method" (constant capital cost throughout the depreciation/operation period of the PV plant) may be used to estimate the cost of the energy produced by PV power plants. According to this method (see, [41]) the present PV energy costs in Central Europe are ca. $ 1.2/kWh. At sites with higher insolation, e.g., in the southwest United States, these costs are ca. 40 c/kWh. For cost-competitive "bulk" power generation, PV-system cost would need to decrease to ca. $ 1/W(peak), if conventional energy cost remains in the present range. This goal might be achievable only with thin-film solar cells (see also [37]).

Figure 51. Investment cost of PV power plants
A) 340 kW(peak) plant at Kobern – Gondorf, Germany [52];
B) 300 kW(peak) plant at Austin, Texas [53]

As can be seen from Figure 51 the BOS cost is nearly as high as that of PV modules. The reduction of BOS cost, therefore, is of equal importance and presents a technical challenge that will be as difficult to meet as the lowering of PV-module cost.

4.10.3. Energy Payback Time

Only a limited number of studies allow an insight in methods, basic parameters, and conditions of the calculation of energy payback time. These have been summarized in [54]. For complete grid-connected systems – PV generator, supporting structure, and inverter – the energy payback times for different solar cell techniques and supporting structures, including tracking and concentration, are in the range of three to five years. These results indicate, that – also with

respect to energy payback – a clear winner of PV systems technology cannot be determined at present. Nevertheless, a tendency favoring thin-film cells seems to exist.

4.10.4. Multifunctional Use of PV Modules

The economic situation of photovoltaics can be considerably improved by multifunctional use of PV modules as, e.g., with PV roofs and PV facades. In these cases additional cost-reducing factors exist:

1) No ground consumption by PV, no ground cost
2) Low cost for supporting structures
3) No extra building for power conditioning systems and controls
4) Vicinity to consumer of electrical energy

For PV roofs stand-off mounting is preferred at present, however, the final goal should be roof integration of solar modules which saves at least the cost of conventional roofing tiles.

The situation is even more favorable for PV facades. Conventional facades are often considered not only to be a purely functional element of a building, but also an architectural ornament. Remarkably high investments, $< \$\,2000/\mathrm{m}^2$, are being made thus allowing PV facades to easily compete. If the total cost of a PV facade is assigned to the constructional part, then the energy-generating part can be considered as almost free of charge; a highly favorable prospect.

5. Photoelectrochemical Solar Energy Conversion

Besides the semiconductor solid-state contacts used in photovoltaics, the semiconductor – electrolyte contact can also be used for conversion of light energy into electric power [55–63]. However, in semiconductor electrochemistry, a charge transfer from the electrode to the electrolyte has to take place in addition to the current flow through an external circuit. This charge transfer can be utilized by inducing a battery reaction. Here, a direct conversion of solar into chemical energy is possible (*Redox Solar Battery*) [64]. A direct conversion of solar energy into a *storable fuel* is also possible by direct water electrolysis, carbon dioxide reduction, etc. For example, the direct water splitting reaction by solar energy as first reported in 1972 [65] resulted in increased interest in this type of energy conversion and in the number of research papers published in this field.

Figure 52. Regenerative photoelectrochemical (PEC) solar cell
A) Principal setup; B) Electron energy diagram for an *n*-semiconductor – electrolyte – metal configuration

The history of photoelectrochemistry dates back to 1839 when E. Bequerel discovered a photovoltaic effect illuminating a platinum electrode covered with silver halide in an electrochemical cell [66]. However, for improved investigation of the "Bequerel photovoltaic effect" [67] the growth techniques to produce high quality semiconductor crystals had to be developed (→ Semiconductors, Chap. 4.2.). The investigations of the germanium electrochemistry began in the mid-1950s [68] which led to the development of basic theories during the early 1960s. In particular, Heinz Gerischer and Rüdiger Memming must be mentioned. However, despite

research for more than 30 years, many fundamental problems still remain to be solved [69].

Photoelectrochemistry has found a new interest in two fields known for many years but which have made progress since 1990; dye sensitization and solar detoxification. The efficiency of the conversion of light to electricity by solar cells with a large band gap semiconductor *sensitized by organic metal complexes* has been continuously improved. Solar efficiencies of at least ca. 10.5 % have been achieved which, in connection with very cheap preparation techniques for the very rough surfaces required, could eventually make them superior to conventional solar cells [70]. *Solar detoxification* has reached a large-scale testing phase although many fundamental problems remain to be solved. Fundamental research is also needed in the promising fields of *direct conversion of solar light into storable fuels*, where the possibility of catalysis is still an open question.

5.1. Principles of Photoelectrochemical Solar Energy Conversion

The basic principles of semiconductor electrochemistry are described in several review papers (e.g., [55], [57], [60], [61]) and a few text books [56], [58], [62], [63]. The important equations and fundamentals have been summarized and an appropriate terminology was recommended by IUPAC [55]. The only difference between a photoelectrochemical and a photovoltaic device is that in photoelectrochemistry (PEC), a semiconductor – electrolyte junction is used as the active layer instead of the solid-state junctions in photovoltaics (see Fig. 52). In both cases, a space charge region is formed where contact formation compensates the electrochemical potential differences of electrons on both sides of the contact. The position of the band edges of the semiconductor at the interface can be assumed in a first approximation to be dependent only on the pH of the solution and independent of the potential (Fermi level) of the electrode or the electrolyte. Hence, upon illumination, *electrons in the conduction band* of the semiconductor reach the electrode surface and can reduce redox couples whose redox potentials are located below the conduction band (i.e., their electrochemical potential U is more positive). *Holes in the valence band* can oxidize species with a redox potential more negative than (i.e., above) the band edge of the valence band at the interface. However, the thermodynamic requirements as described by the positions of the quasi Fermi levels have to be fulfilled in addition (compare Fig. 54).

Using these principles two types of PEC cells can be built. If the redox system oxidized at one electrode is reduced (regenerated) at the counter electrode, the *regenerative PEC cell* can convert light energy into *electrical energy* (Fig. 52, Table 2). If, however, the two half cells are separated, e.g., by an ion exchange membrane, two different reactions can be used to store *chemical energy* directly (Fig. 53, Table 3). Here, the amount of energy stored is determined by the difference in free energy of the two products. The direct water splitting is an especially interesting example which leads to the formation of hydrogen and oxygen with a thermodynamic free energy difference of 1.23 eV.

Table 2 summarizes results obtained for electrical energy production in regenerative photoelectrochemical solar cells on a laboratory scale. Table 3 gives corresponding results for the few yet published so-called photoelectrochemical solar batteries. Here the efficiency includes already all losses for the storage reactions. Since the cells have not been tested in all cases under standard conditions, the efficiencies are only an approximate guide. However, since comparably insignificant amounts of money and man power have been expended, and all experiments were performed under very crude laboratory conditions, these results are quite remarkable and prove the high quality of the semiconductor – electrolyte junction.

The energy diagrams as shown in Figures 52 and 53 display n-type semiconductor – electrolyte – metal configurations. However, p-type materials and a combination of both types (n-semiconductor – electrolyte – p-semiconductor) can also be used. As depicted in Figure 54, the latter type appears similar to $p-n$, the other configurations similar to semiconductor – metal Schottky junctions.

In photoelectrochemistry the currents of the majority carriers (i.e., electrons in the n layer and holes in the p layer) are, in most cases, determined by the charge transfer kinetics to the redox species in solution. These currents are loss currents for solar energy conversion since they diminish the needed minority carrier currents flowing in the opposite direction. However, in photoelectrochemistry are in general smaller than those found for semiconductor – metal contacts since, generally in solid state contacts, charge transfer at the interface is infinitely fast [84]. In principle this decrease in majority carrier transfer rates at the semiconductor-electrolyte interface is the reason for the high conversion efficiencies of PEC cells as shown in Table 2.

The results obtained for the *direct water splitting reaction* have been much less promising. The following conditions must be fulfilled for a direct solar energy conversion into a storable fuel: The photovoltage (splitting of the quasi Fermi level under illumination) must be larger

Figure 54. Formation and use of a depletion layer and it's electric field when a semiconductor connects to an electrolyte
E = electron potential; $-E$ = electron energy with respect to the vacuum level; E_C = lower conduction band edge; E_V = upper valence band edge; E_F = Fermi level; $E'_{F,n}$ and $E'_{F,p}$ = quasi Fermi levels of electrons and holes, respectively, under illumination ($h\nu$); E^0 = standard redox potentials of the redox couples indicated
A) n- and p-type semiconductor of the same kind before contacting the electrolyte; B) Equilibrium situation in the dark with both semiconductors forming a space charge layer at the surface compensating the chemical potential difference of electrons in the three materials; C) Photovoltage formation (splitting of the quasi Fermi levels $E'_{F,n}$ and $E'_{F,n}$) under illumination enabling direct water splitting

than the voltage necessary to drive the electrolysis – i.e., the free energy stored in the products (1.23 eV for water splitting under standard conditions) – plus the necessary overvoltages to run the reactions at a given current density (see Fig. 55). From photovoltaics, the photovoltage is considerably smaller than the band gap (ca. 0.5 V) due to recombination processes. In addition, for direct water splitting the band positions at the semiconductor – electrolyte interface have to be located at an energetically suitable position. The conduction band edge needs to be located negative (on an electrochemical scale) enough above the reduction potential of water (E_{H_2/H^+} plus the necessary overvoltage), the valence band edge positive enough below the oxidation potential of water (E_{OH^-/O_2} plus the necessary overvoltage) to enable the charge transfer.

Figure 55. Band edge positions of semiconductors as determined in photoelectrochemical experiments in aqueous solutions The values on the left are literature data whereas the values obtained in the dark (d) and under illumination (l) in the right half of the diagram were determined in the author's laboratory
For each material the band gap between the lower conduction and the upper valence band edge is shown as it is fixed at the semiconductor – electrolyte interface. For comparison, the vacuum energy scale as used in solid state physics and the electrochemical energy scales, with respect to a normal hydrogen electrode (NHE) and an saturated calomel electrode (SCE) as reference points, are shown as well as the standard redox potentials of water in acidic solution

As shown in Figure 55 for an arbitrary selection of semiconductors, this requirement is fulfilled by only few of the classical semiconductors even if it is assumed that the necessary overvoltages are zero – although they are usually very high at semiconductor electrodes. These extraordinarily high overvoltages are probably the reason why even among these few suitable semiconductors only strontium titanate ($SrTiO_3$) is really able to directly split water.

However, concerning the problem of necessary overvoltages, latest results obtained with multiple nano contacts have shown that a key problem of direct water splitting has actually been solved, i.e., that of catalyzing the charge transfer of minority carriers without increasing the rate of majority carrier losses at the interface. As described above these loss currents are detrimental in the case of semiconductor-metal contacts. Therefore, using metals as catalysts in order to improve the reaction kinetics for hydrogen or oxygen formation in principle will always lead to low solar efficiencies, if real Schottky-type contacts are formed. This problem was recently overcome by depositing nano-sized metal particles as *multiple nano contacts* onto the semiconductor surface [115], [116]. This now may open new ways to again approach the "stuff that photochemists' dreams are made of", the photochemical decomposition of water [117].

5.2. Dye-Sensitized Photoelectrochemical Solar Cells

Charge transfer from light-excited organic molecules to a semiconductor with a large band gap has long been known (→ Photography, Chap. 2.2.1.) and is the basis of photography. Here, silver halide crystallites are sensitized by organic dye molecules. Although many studies have been performed on these materials the actual mechanism of dye sensitization remained unclear until electrochemists started investiga-

tions in electrolyte solutions using single crystalline semiconductor electrodes [85]. As a result [86] it became apparent that only the first monolayer of dyes directly adsorbed on the semiconductor surface is able to inject charge carriers into the semiconductor. As shown in Figure 56 light of a wavelength too long to be absorbed by a large-band-gap semiconductor electrode can be absorbed by a dye molecule (D) on the surface. If the excited electron (on D∗) is injected into the conduction band of the semiconductor (leading to the oxidized dye D^+), it can be used to create a photovoltage (eU) in a typical photoelectrochemical setup consisting of a semiconductor electrode and a metal counter electrode connected via an external load and immersed into an electrolyte. Here, the current through the electrolyte is carried by a redox couple (red/ox) which determines the potential of the counter electrode and also reduces the oxidized dye molecule (D^+) back to its ground state (D).

Although the quantum yield of this process can be higher than 90 % [87] the small overall light absorption of a dye monolayer limits the photocurrent efficiency with respect to the incident light to a value well below 1 %. Therefore, a few attempts have been made to increase the surface area by using sintered electrode materials [88]. However, these attempts were quite unsuccessful.

A breakthrough only became possible after Stalder and Augustynski succeeded in preparing highly porous TiO_2 electrodes in a sol – gel process [89]. Using these electrodes a surprisingly high light to current conversion efficiency was obtained [90]. Improvements of this system with respect to electrode preparation, type of organic ligands of the ruthenium complex used as sensitizing dye, and the solvent used for the I^+/I_3^- redox couple led to solar efficiencies of about 11 % [118], [119].

Since further improvements seem to be possible, the sensitized photoelectrochemical solar cell based on a sol – gel semiconductor and transparent conductive oxides (TCO) on glass is very promising because the production costs are expected to be low. Therefore it may become the first practical application of photoelectrochemical solar energy conversion. Nevertheless, important problems still have to be solved such as the scale-up of today's laboratory processes. Furthermore, the reported stability and efficiency has to be proven in practical applications.

5.3. Solar Wastewater Detoxification

The first large-scale applications of the semiconductor – water interface have been tested in the United States and in Spain. Researchers of Sandia National Laboratory were testing the use of TiO_2 suspensions in a large-scale decontamination plant in New Mexico; Lawrence Livermore National Laboratory performed field experiment in California where in phase II of the experiment two strings of concentrating trough reactors were operating, each about 35 m long. In this program ca. 160 m^2 of

solar concentrator enables treatment of toxic organic wastewater with a maximum flow rate of 100 L through transparent tubes mounted at the focus of a reflecting parabolic trough containing the photocatalysts (Fig. 57). Powered by energy from the ultraviolet end of the solar spectrum, the catalyst produces oxidizing agents in the water (D^+) that react with the contaminants; the hazardous chemicals are converted to compounds such as water, carbon dioxide, and dilute acids that are easily neutralized. In order to maintain in electrical neutrality, a reduction process has to occur in addition (forming A^-), in most cases the reduction of oxygen.

Figure 57. Solar detoxification
A) Principal setup; B) Very rough energy scheme of a semiconductor particle

A smaller but somewhat broader research program was conducted in the European solar test center Almeria (SOTA) in Spain. Among other solar high temperature and solar chemistry projects in the Plataforma Solar de Almeria there were also investigations concerning the solar detoxification of polluted wastewaters. European Community collaboration in this field has been extended by the Avicenne program to include several other Mediterranean countries, e.g., Israel and Morocco.

All large-scale programs so far are conducted in concentrating systems (see Section 4.3) even though several studies showed a decreased photocatalyst efficiency at higher illumination intensities [91].

Starting in Japan, niche applications of photocatalytic decomposition of organics [120] found widespread industrial interest, e.g., for deodorization, sterilization, disinfection and window cleaning. In Japan several companies are already producing bathroom tiles based on TiO_2 photocatalysts that work under illumination with room light or, e.g., filter papers for air conditioners under UV lamp illumination. Since TiO_2 films can be prepared colorless and transparent, all lamps illuminating traffic tunnels in Japan will be provided with glass covers which are photocatalytically self cleaning from exhaust deposits.

However, the use of TiO_2 catalysts limits the use of solar light to the far UV range of the solar spectrum and thus to efficiencies below 5 %. Therefore the question arises whether other materials can be used. Since the intermediate formation of OH radical seems to be important, mixed oxides of titanium and iron were investigated. Indeed, the absorption of light can be shifted considerably toward the visible spectrum by using these catalysts. Further search for other catalyst materials is indicated [121], [122].

5.4. Direct Photoelectrochemical Water Splitting

Despite some sensational papers on direct photosplitting of water using visible light [92], all of the systems reported so far have failed upon more critical examination [93]. Although the corresponding papers have never been withdrawn most experts agree that to date no direct water splitting has been achieved in a nonassisted process using visible light. Even with TiO_2 a bias voltage is necessary to achieve si-

multaneous evolution of hydrogen and oxygen. This concept of *photoassisted electrolysis* can of course be applied to nearly all electrode materials. In principle, the same concept is used if working and counter electrodes are immersed in electrolytes of different pHs and redox potentials or if semiconductor arrays of several contacts in series are combined to obtain the decomposition voltage in a several photon process [123].

Figure 58. Theoretical solar (AM 0) efficiency of photoelectrochemical water splitting versus the band gap of the semiconductors used [123]
A) Using one semiconductor and a metal counter electrode; B) Using *p*- and *n*-type materials of identical band gaps as the two electrodes
Curves are calculated for (a) zero, (b) 300, (c) 500, and (d) 700 mV combined overvoltages for both oxygen and hydrogen evolution. Envelope gives the data for an optimum *p*–*n* photovoltaic device

As shown in Figure 58, a higher efficiency than that obtainable in a one-photon water-splitting system is achievable using two photons per transferred electron in a system with two effective junctions of semiconductors with a smaller band gap. The only successful approach to use a combination of *p*- and *n*-type semiconductor–electrolyte contacts for water splitting has been that of Inoue and Yamase using the large-band-gap semiconductor SiC [95]. Unfortunately, even this material is not stable against anodic dissolution.

As demonstrated for many systems, most modifications of the semiconductor–electrolyte interface needed to improve the charge-transfer kinetics finally lead to solid-state semiconductor junctions immersed into an electrolyte [96]. The only practical system which has ever come close to production, the Texas Instrument's *p*–*n*-silicon solar arrays for direct splitting of HBr, is a multijunction solid state device, as pointed out by Bard and coworkers [97].

It was already recognized in the early days of photoelectrochemistry [98] that metals deposited at the semiconductor–electrolyte interface may act as catalysts for charge-transfer reactions. However, it has only recently become possible to investigate the metal-modified semiconductor–electrolyte interface in more detail due to the development of very advanced in situ techniques. If the modification of the semiconductor–electrolyte interface by metals is really necessary for the catalysis of hydrogen or oxygen evolution, and if this modification leads to the formation of a Schottky junction, then the good quality of the photoelectrochemical interface is traded against a low-quality semiconductor–metal junction as pointed out above. The crucial question, therefore, is whether the advantages of both types of contacts may be combined and the disadvantages avoided. This is indeed the case as has been shown only very recently [80] on the basis of ideas developed by Y. Nakato, H. Tsubomura, and coworkers [79], [99]. They proposed that by decreasing the size of metal islands contacting a semiconductor surface, the barrier height of the semiconductor–electrolyte interface surrounding the metal may increase the otherwise too small barrier of the semiconductor–metal Schottky junction. Thereby the high loss currents that normally occur at the semiconductor–metal junction may be avoided. This has now been implemented by Meissner and coworkers us using GaAs

electrodes modified by multiple nano contacts (MNCs) formed from colloidal metal solutions [100]. By carefully avoiding all free metal during the MNC deposition a dramatic potential shift of the photocurrent onset for hydrogen evolution at *p*-GaAs has been realized without increasing the majority carrier loss currents.

6. Economic Aspects

The economic efficiency of an industrial system can most simply be defined as the ratio of costs to effectiveness. The effectiveness of an energy system is generally considered equal to the energy produced by the system. Economic efficiency is thus the ratio of costs to energy produced, that is, the unit energy production cost. This quantity allows a comparison between different energies to be made. The most important components of the energy production cost are (1) capital costs as a function of depreciation life of facilities and interest rates, (2) maintenance, upkeep, and other operating costs including personnel, and (3) fuel costs. The cost structure of solar technologies is generally characterized by high capital costs and low operating costs. Usually no costs are incurred for fuel, unless biomass is used. Economically, the use of solar technology means the substitution of capital for future fuel costs. Investment costs and financing conditions essentially determine the costs, while the present and future prices of fuel saved basically define the economic utility.

Any assessment of the costs of solar technologies must take account of the present level of development (most such technologies are novel). Solar technologies can be classified in three groups [127]:

1) Systems now on the market
2) Systems ready to go on-line
3) Systems still in development

The first group comprises *facilities fully developed* and already in commercial use; the costs and capabilities of these are accurately known. They are manufactured on an industrial scale, though mostly in relatively small quantities. This category includes wind-energy plants ($300-1000\,\mathrm{kW_e}$), small photovoltaic modules ($\leq$ a few $\mathrm{kW_{peak}}$), passive solar systems for new buildings, solar swimming pool heating, solar collectors for water heating, solar-thermal trough collector power plants that have been operate successfully in California since 1986, and last but not least biomass plants in the $\mathrm{MW_{th}}$-size for district heating and cogeneration with steam turbines. If long depreciation periods and low interest rates are assumed, systems of this category are now economically efficient. In order to further improve the competitiveness of these systems, continued development work aims at lowering the manufacturing costs by introducing more rational production methods and increasing the number of units produced. A prerequisite for this is a substantial, self-sustaining growth in demand for solar energy technologies, and given the very low prices for other energies now in effect, this is possible only with governmental support or a change in energy prices.

The group of systems *ready to go on-line* include the following, which have been tested on a pilot scale and demonstrated in individual facilities: larger wind-energy plants ($> 1000\,\mathrm{kW_e}$); photovoltaic power plants (up to $\mathrm{MW_{peak}}$-size); large thermal collector systems on buildings and on the ground, with seasonal storage for heating and hot water (solar district heating); passive systems with transparent thermal insulation; solar process heat systems; paraboloid mirror systems with Stirling engines or gas turbines, and biomass gasification plants to feed engines or gas turbines. At present these systems are not economically efficient in comparison with fossil fuels. Experience based on the operation of test and demonstration facilities is not, by and large, sufficient to indicate accurately the capacity of a plant or guarantee completely reliable service. The technical and economic development objectives for these individual technologies are well-defined and are certainly considered attainable. Essential for the future of these approaches, in particular, is to carry out a sufficient number of demonstration projects under realistic service conditions and to open the commercial markets.

The *third category* of systems, which are, at present, definitely in the development stage, includes large photovoltaic power plants in the multimegawatt range; novel solar cells; trough collector power plants with direct steam generation; solar thermal tower plants; and hydrogen technologies such as fuel cells. These systems cannot be operated economically yet. Their technical and economic potential, however, is undisputed.

∗ All figures are mean values of a bandwidth of technology size
1 = Investment cost per unit capacity (cost of PV is referred to peak output)
2 = Investment cost per unit generated (= 1 divided by rated hours per year)
3 = Specific cost of electricity (interest rate 6 %, depreciation period 20 years)

Many scenarios for national and world energy supply strategies accord great importance to solar technologies and regenerative forms of energy in general [127, 129–133]. Hydroelectric power, biomass, wind power, geothermal energy, and all technologies for the direct utilization of solar radiation are important options for the future energy economy. They meet both the needs of developmental policy and global environmental requirements. Solar technology costs that are achievable in the medium to long term are therefore significant in the economic assessment, at least as much as current costs. Table 4 summarizes present and future investment and specific electricity costs for some of the most important solar electricity generation technologies.

Figure 59 [135] gives an overview of typical heat production costs (in 0.005 €/kWh$_{th}$) from biomass, biogas, and solar thermal collector systems of different size. Their heat production costs have to be compared with the costs of heat production from natural gas or oil, which are presently about 0.05 €/kWh. Biomass plants utilizing residues or cheap wood are competitive already with heat production from oil and gas. Present solar-thermal collector systems are far too expensive, but they show a large cost reduction potential with growing mass production. Wind energy is an impressive example of technical improvements that have been introduced with simultaneous cost reduction within only a few years (Table 5). The same development can be observed with photovoltaic modules (Figure 60) [134]. Since 1978 the world market of photovoltaic modules has increased at an annual growth rate of about 15 % and has surmounted the 100 MW$_{peak}$/a level in 1997. In the same period the module prize has fallen from about \$ 25 /W$_{peak}$ in 1978 to about \$ 4/W$_{peak}$ at present. Since the time when photovoltaic modules were first introduced for satellite power supplies in the 1970s, costs have even dropped by more than a factor of 100. The trough collector power plants erected in California from 1985 to 1990 (Table 6), too, showed a sharp decline of electricity costs within only a few years. New trough collector power plants of 200 MW$_e$ size built up now could generate solar electricity with \$ 0.1/kWh in an entirely solar mode, and with \$ 0.07/kWh in a hybrid mode where gas produces one half of the total annual electricity (see also Table 4).

In view of the usual intense focus on costs, the economic analysis of solar technology actually reduces to a pure cost analysis, a narrowing that often fails to deal with the complex assessment

Figure 59. Specific heat production cost of biomass, biogas, and solar thermal collectors (interest rate 4 %, depreciation period 15 a; cogeneration with credit for electricity production)

Figure 60. Global market and prices of photovoltaic modules since 1978 [134]

problem. The question of economic efficiency is always a matter of judgment and depends heavily on the situation in which the decision is made as well as the possible alternatives. Alternatives to solar technologies, in most cases, are conventional energy systems based on fossil fuels. A comprehensive evaluation of technical alternatives would have to take in the following points quantitatively or at least qualitatively:

Economic role of the operator
- Private household
- Private company
- Power supply utility
- Municipality
- Other

Purpose of power generation
- Own use
- Sale of power, heat, steam, etc.

Analysis of systems as to energy conservation
- (energy service)

Table 5. Development of plant technology and costs of wind energy [135]

Plant size, kW/a	150 (1990)			300 (1991)			600 (1993)			1500 (1997)	
Rotor diameter, m	23			31			44			63	
Mean annual wind velocity m/s (10 m)	5	6	5		6	5		6	5		6
Annual electricity production, GWh/a	0.31	0.44	0.58		0.87	1.20		1.80	2.91		4.70
Investment costs (€/kW$_e$)	1200			1020			870			840	
Specific electricity costs[a] (€/kWh)	0.146	0.107	0.127		0.08	0.102		0.069	0.09		0.064

[a] Interest rate 6 %, depreciation time 10 years, maintenance, insurance 4 % of investment per year.

These points must be added to the assessment from the viewpoint of the individual enterprise. On the overall economic level, not only the internal costs and constraints considered in present-day business calculations, but also the external or social costs of energy systems and the general economic conditions must be considered [144]. These include:

1) Emission of air pollutants
2) Emission of greenhouse gases
3) Generation of wastes that are difficult or impossible to dispose of
4) Potential hazards due to the facility as well as upstream and downstream processes
5) Noise emissions
6) Land area required
7) Import dependence
8) Reliability of supply
9) Renewability of resources

If damages and other costs are borne by the national economy without having any cost impact on the polluter, the result will be nonoptimal allocation of resources. The state will then have to ensure that competitive imbalances are offset by imposing the external costs. This can be done in two ways: indirectly through regulations that force the operator of an energy facility to take measures to comply with certain limits (an example is the *TA-Luft* air pollution regulation), or directly through user fees and/or taxes (such as fees on carbon dioxide emissions from fossil fuel systems, now under discussion). The external costs of solar technologies are only a small fraction of those of the conventional alternatives when the latter can be estimated at all. This neglection of external costs gives solar technologies a substantial competitive disadvantage, which hinders their introduction in the market.

A number of publications have given projected costs for solar energy generation [142], [126], [127], [128], [131], [136]. Table 7 gives an example. If the goal is that solar energy utilization grows rapidly up to the year 2010 (13 % share), the unit energy cost level would have to double relative to the present for solar technologies to be competitive. Solar heat from a variety of sources would then be, on average, twice as expensive as fossil fuels today (1998). The costs of a solar energy mix (hydro, wind, biomass, biogas, and photovoltaic) would be ca. 50 % higher

Table 6. Technical data and power generation costs for trough collector power plants (Solar Electricity Generating System = SEGS plants I – VIII) in California since 1985 [139], [137], [140].

	Plant							
Data	I	II	III	IV	V	VI	VII	VIII
First full year on line	1985	1986	1987	1987	1988	1989	1989	1990
Net power, MWe	13.8	30.0	30.0	30.0	30.0	30.0	30.0	80.0
Collector field area, 1000 m^2	83	189	230	230	233	188	194	464
Turbine efficiency, %	31.5∗	29.4	30.6	30.6	30.6	37.5	37.5	37.5
Energy output, GWh/a∗∗	30.1	80.5	92.8	92.8	91.8	90.9	92.6	253.4
Energy cost, c/kWh	30.0	22.9	18.0	18.0	18.0	15.5	13.8	12.5

Table 7. Energy generation costs [a] of renewable forms of energy with increasing utilization [126], [143] (€/kWh_{th} or €/kWh_e; 4 % interest rate)

	1988 [b]	2010	2030	2050
Electricity, €/kWh	0.046	0.070	0.114	0.143
Heat, (average)	0.042	0.081	0.157	0.165
Electricity	0.090	0.138	0.223	0.280
Direct heat	0.040	0.077	0.089	0.104
Hydrogen			0.315	0.271
Fuel	0.100	0.200 [c]	0.270 [d]	0.278 [d]
Final energy costs, (average)	0.064	0.123	0.175	0.220
Relative to 1988	1.0	1.92	2.73	3.44
Total final energy consumption (1988 = 1)	1.0	0.69	0.65	0.55
Absolute energy costs (1988 = 1)	1.0	1.33	1.78	1.89
Gross domestic product (GDP) (1988 = 1)	1.0	1.52	1.90	2.28
Ratio energy costs: GDP (1988 = 1)	1.0	0.88	0.94	0.83
Share of renewable energies in final energy consumption, %	2	13	36	69

[a] Includes generation, transport, storage, and distribution.
[b] "Electricity" includes generation and distribution costs; "heat" includes mixture price of fuel oil and gas; "fuels" includes mixture price of gasoline and diesel; fossil energies include consumption taxes but not value-added tax.
[c] Fossil.
[d] Liquid hydrogen from hydro and solar.

than present costs of electricity from conventional sources.

Even as the costs for the individual plants involved in solar technology decline, the growing use of solar energy will result in further cost increases because of greater expenditures on storage and conversion of solar power into a distributable form. If renewable forms of energy gain a 70 % share in the year 2050, the unit cost level will be a factor of 3.4 higher than today (1998). If unit energy expenditures are put together with the final energy consumption figures in this scenario, the absolute outlays for energy will rise only ca. 30 % by 2010 (relative to the present) and 80 – 90 % in the longer term. The fraction of gross domestic product (GDP) spent on energy will remain largely constant, since the GDP will rise further in the projection period. New investigations confirm these basic statements [127], [143]. It can thus be concluded that solar energy systems are affordable for industrialized economies.

Energy price rises now planned, and thus those foreseeable for the economy, will mobilize great potentials for more conservative energy use and will promote innovations that may have beneficial effects not only on the energy industry but on the economy as a whole. Increases in energy prices decreed by the government result from passing on external costs, as mentioned above. As long as the sum of taxes and fees imposed does not exceed the environmental damage costs, a national economy in which solar energies are widely used and environmental pro-

tection is actively pursued will not sustain any economic injury. In the long term, conservation of resources and the environment through the use of solar power, together with the social benefits of such technologies, will represent a major benefit that will justify such expenditures.

1. Introduction

Soldering and brazing are thermal processes for joining and coating materials, in which a liquid phase is produced by melting a solder or a brazing filler metal or by diffusion to the boundary surfaces (e.g., to form a eutectic). The temperature remains below the solidus temperature of the base material (DIN 8505, Part 1).

Alloys or pure metals are used as solders or brazing alloys. Where their liquidus temperature is <450 °C the process is called soft soldering, and where it is >450 °C it is known as *brazing*. In *high-temperature brazing*, the operation is carried out in the absence of a flux and air, and the bonding metal has a liquidus temperature >900 °C.

A major difference between soldering and welding is that only the filler material (i.e., the solder or brazing alloy), and not the base material, is melted. This means that solders must have an appreciably lower melting range than the base material. In industrial soldering and brazing, groups of specially developed alloys are usually used (see Chap. 4).

The molten filler metal must come into intimate contact with the base material to allow formation of metallic bonds. Oxide layers exist on all industrial metal surfaces and must therefore first be broken down and removed. When soldering or brazing in air, this is done by covering the area to be joined with a flux in which the oxides dissolve at the working temperature. When brazing in the absence of air, i.e., in a protective gas or vacuum, the oxide layers can be cracked under suitable conditions without a flux.

If the base material has a clean metallic surface, it can be wetted by the liquid filler metal provided that solid solutions or intermetallic compounds are formed. The filler metal then spreads over the area to be joined, and solidifies to form a strong bond with the base metal. The lowest surface temperature at which this process takes place is known as the *working temperature*, and is a characteristic parameter for each filler metal.

Brazability denotes the capability of a workpiece to be manufactured to given specifications by a brazing process (DIN 8514). It is a function of

1) The suitability of the base and filler materials needed for a brazing operation
2) The stability of the brazed joint as a function of design
3) The possibility of including a brazing operation in the manufacturing process

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a24_427

These factors can influence each other. If only one of these conditions is not completely satisfied, the brazability of the workpiece may be jeopardized.

Figure 1. Capillary pressure of a silver solder at 650 °C as a function of gap width

2. Theory

Soldering and brazing are processes in which materials are thermally joined by melting a supplementary material (solder or brazing alloy); the base material is not, however, melted. This definition is not adequate because the liquid filler metal cannot wet the substrate unless at least three other conditions are satisfied:

1) The joining surface and the filler metal must be bright (i.e., clean and free of oxides)
2) The joining surface and the filler metal must be at or above the working temperature
3) At least one component of the filler metal must react exothermically with the substrate to form an alloy or compound

The surface of the workpiece to be joined is heated as uniformly as possible until the working temperature is exceeded. There should be an even temperature distribution; this is not necessary for welding.

If the conditions for wetting are satisfied, a mixed crystal or a compound is formed between the substrate and the liquid filler metal, starting in a region of only a few atomic layers. The liberated energy is sufficient to overcome the surface tension of the drops of solder, allowing them to spread. As systems always tend towards a state of minimum potential energy, the filler metal spreads and fills the gap between the jointing faces of the workpieces to be bonded. The filler metal spontaneously penetrates into narrow gaps against the force of gravity, the force responsible for this is termed *capillary tension*. The magnitude of the capillary attraction depends mainly on the width and geometry of the gap to be joined. In the case of a parallel gap, it is inversely proportional to the width (Fig. 1). If the cross section of the capillary is triangular (e.g., when a knurled bolt is brazed into a drilled hole), the capillary pressure is approximately three times the filling pressure for a parallel-sided gap.

If a flux is used during brazing or soldering, the minimum gap width is determined by the minimum volume of flux which must be available in the gap to ensure dissolution of the oxide layer on the surface. Practical experience shows that this is assured for gap widths as low as 0.05 mm. If brazing is carried out in a protective gas or vacuum, gaps can be smaller, and can be so narrow that the surfaces come into contact. In this case the capillary pressure is therefore high and ensures spontaneous, reliable filling of the gap with solder. The minimum gap width is then determined by the metallurgical processes, including alloy formation, that take place between the filler metal and the substrate [7]. Isothermal solidification of the filler metal may occur before the gap is completely filled, especially in narrow gaps.

The maximum gap width is determined by the capillary pressure necessary for the liquid filler metal to penetrate against the force of gravity, and to stay in place. If the molten filler metal is to flow spontaneously into the gap (mechanized brazing or furnace brazing), the width must not exceed 0.2 mm. In the case of manual soldering or brazing, a gap as high as 0.5 mm is permissible, since the operator is able to correct irregularities. Indeed, gap widths exceeding 0.5 mm can only be filled with filler metal manually, and require special skills. In this case, the surfaces to be joined are not heated evenly, heat is applied to the workpiece at individual points, as with gas welding. This technique is known as braze welding to distinguish it from gap brazing. It is not of great practical significance compared with gap brazing, apart from its use for installing galvanized steel pipes.

Apart from its use as a bonding technique, soldering as well as brazing is used for coating surfaces with filler metal or other components. The coating can be used for protection

against corrosion or abrasion. Alternatively, it can be employed as a method of constructing or shaping workpieces (e.g., uneven surfaces in the steel bodywork of an automobile can be smoothened by coating with soft solder, eroded turbine blades can be repaired by coating with high-melting brazing alloys).

In the production of abrasive tools or nonslip surfaces, particles of hard materials (e.g., tungsten carbide, ceramics, or diamond) are embedded in a braze matrix and applied to the surface. Nonmetallic hard materials can be wetted with special filler metals [8].

Abrasion-resistant coatings can be produced by brazing the surface with very hard materials (e.g., nickel-based brazing alloys). Abrasion resistance can be further improved if finely divided hard materials such as tungsten or chromium carbides are incorporated into the coating [9].

3. Soldering and Brazing Processes

Soldering and brazing processes can be classified on the basis of different criteria, for example according to the type of filler metal, as described in Chapter 1: soft solders, brazing filler metals or high-temperature brazing alloys. Classification according to coating by brazing and bonding by brazing has also been mentioned (Chap. 2). Soldering and brazing processes are described in this chapter according to their energy source.

3.1. Soldering Bits and Blocks

When soft soldering, the parts to be joined can be raised to the required temperature by heating with a soldering bit or "iron," which is usually made of copper. The bit generally has a pointed end whose geometry matches the shape of the workpiece. Heat transfer takes place via the molten solder and the flux. The flux can be present as a filling inside a "cored" solder, or added separately. Soldering with a bit is usually performed manually, but automatic devices are also known.

In block soldering heat is applied evenly to the surface of the workpiece. The parts to be joined are usually presoldered, and are placed on a heated metal block (e.g., a hotplate) until the soldering temperature is reached. This method is useful for soldering heavy-section components to thin metal sheet [10].

3.2. Soldering Baths (Dip Soldering)

In soldering baths, which are usually heated electrically, the liquid solder transfers the heat. A flux is first applied to the workpiece, which is then immersed in the soldering bath. In the bath solder is applied simultaneously at several joints in a single dipping operation. Baths are therefore used in electronics as a simple means of automating soft soldering (e.g., motor armatures and simple electronic circuits). The soldering temperature is precisely controlled by adjusting the temperature of the bath. This process is mainly used with soft solders, but there are some applications in which baths of brazing filler metal are used (e.g., for preplacing filler metal for a subsequent brazing operation). These baths are covered with a layer of molten flux to protect them from oxidation.

Figure 2. Principle of wave soldering
a) Pull-through angle; b) Solder bath with solder wave; c) Drying zone; d) Printed circuit board; e) Flux bath (fluxing station with foam wave)

3.3. Wave Soldering

In wave soldering a flow pattern is produced in a soft solder bath by a pump in such a way that a stationary wave is formed on the surface of the bath. This soldering process is typically used for mass production of circuit boards for electronic components. The wave soldering bath is usually preceded by a flux bath with a similarly generated surface wave (Fig. 2).

3.4. Reflow Soldering

The reflow process involves the remelting of solder which has been preplaced on the area to

be soldered before final soldering takes place. Heating is carried out in various ways, e.g., by high-temperature oil, steam, or IR radiation. In contrast to the soldering methods described in Sections 3.1, 3.2, 3.3, the placing of the solder and the heating of the workpiece take place at different times. The process has become more important with the increasing miniaturization of electronic components. For example, a solder – binder paste, with or without a flux, is applied by screen printing in exactly controlled amounts and conforming exactly to the shape of the workpiece. The advantages of this procedure are exploited in the surface-mounted devices (SMD) technique, in which the components do not have connector wires, but are soldered flat onto the surface of a circuit board on which the solder has been preplaced.

3.5. Flame Soldering and Brazing

In flame soldering and brazing, heating is carried out by the combustion of a gaseous mixture (e.g., natural gas, propane, or acetylene with air or oxygen). Special burners are used either directly or indirectly to heat the areas to be joined to the working temperature. For soft soldering, indirect heating is preferable because a direct flame can destroy the soft-solder flux.

The flame should be adjusted so that it is neutral or slightly reducing. An excess of oxygen must be avoided because of possible oxidation of the joining surfaces.

The size of the burner should be adjusted to the dimensions and thermal properties of the workpiece. During manual soldering or brazing, the burner is moved to provide even heating of the surfaces to be joined, whereas in automated soldering or brazing the workpiece is usually moved.

3.6. Induction and Resistance Brazing

These brazing methods are frequently used in the tooling industry to braze cemented carbide tips of cutting tools. In these brazing processes, electrical energy is converted into heat due to the electrical resistance or contact resistance of the workpiece. In induction brazing, alternating currents are induced in the surface regions of the workpiece. The depth to which these induced currents penetrate into the workpiece decreases with increasing frequency.

Resistance brazing can be carried out by direct resistance heating of the items to be joined, or by indirect heating via special electrodes.

3.7. Salt-Bath Brazing

In salt-bath brazing, the parts to be joined are heated by immersing them in a bath of molten salt (e.g., alkali metal fluorides) that usually possesses fluxing properties. The filler is placed on the parts to be joined before immersion in the bath. This method is widely used for brazing aluminum heat exchangers. Advantages include precise temperature control and even temperature distribution within the workpiece. After brazing, the salt residues must be removed by thorough washing to prevent corrosion; this is a disadvantage of the process from the environmental point of view. The salt-bath process is therefore being replaced by furnace brazing.

3.8. Furnace Brazing

In furnace brazing, the parts to be joined are heated by radiation and by the convection of hot gases in an electrically heated furnace. As manual handling during the brazing process is not possible, the workpieces must be assembled and secured and the filler metal put in position in a preliminary operation. Special equipment is often used to ensure accurate positioning of the surfaces being joined; other possibilities include fixing the parts by tack welding or using parts with a self-centering design. Shaped pieces of filler metal (preforms) can be put in position as a preliminary operation, or the filler metal can be applied to the gap in the form of paste.

Although fluxes are sometimes used in furnace brazing, one of the main advantages of the process is that the use of fluxes can be avoided when suitable protective gas atmospheres are used. The protective gases can be either reducing atmospheres (e.g., H_2 or $H_2 - N_2$ mixtures) or inert atmospheres (e.g., Ar or He), which in some cases must satisfy extremely high purity specifications that depend on the filler metal and the base material. Removal of flux residues is, of course, superfluous when parts are brazed in a protective gas without fluxes. Also, the production of scale on the workpieces is prevented

by the protective gas atmosphere. Brazing in a protective gas can be carried out in continuously operating furnaces in which a conveyor belt of heat-resistant woven wire passes through a tunnel furnace. Brazed parts can therefore be economically mass produced.

Flux-free brazing can also be carried out under vacuum. The quality of the vacuum required is determined by the filler and base materials, and can be between 10 Pa (10^{-1} mbar) and 10^{-4} Pa (10^{-6} mbar). Vacuum brazing can only be carried out batchwise in closed chamber furnaces.

A further advantage of all furnace brazing processes is that precise and reproducible temperature control results in very consistent brazing. Scaling is also minimized by the even temperature distribution of the workpieces. For these reasons, the process is growing in technical and economic importance.

4. Soldering and Brazing Materials

Some properties and uses of selected solders and brazing alloys are given in Table 1.

4.1. Soft Solders

Soft solders have a liquidus temperature below 450 °C. They comprise three groups, which have different areas of application:

1) Lead – tin and tin – lead solders
2) Special soft solders
3) Soft solders for aluminum-based materials

Lead – Tin and Tin – Lead Solders. These solders constitute by far the majority of the soft solders used in industry. The contain 2 – 90 % tin, solders containing 40 – 60 % tin being the commonest. See also → Lead Alloys.

Solders with a high lead content require relatively high soldering temperatures, but permit high operating temperatures, sometimes above 200 °C, depending on strength requirements (e.g., in automobile radiators or heaters). Although these solders are low in price, their soldering properties (i.e., wetting and flow properties) are inferior to those of the high-tin solders. The high-lead solders are mainly applied by flame soldering owing to their relatively high soldering temperature (up to 300 °C and above).

The liquidus temperature of tin – lead solders decreases to ca. 180 °C with increasing tin content, improving their soldering properties. For general-purpose applications, soft solders containing 35 – 50 % tin are used. If a further reduction in soldering temperature is required, the eutectic tin–lead solder (ca. 60 % tin) is used. Its main application is for soldering electronic circuits in a bath [11]. In some solders, part of the tin is replaced by antimony. This improves the mechanical strength of the solder, but the soldering properties are not quite as good.

Special Soft Solders. Special soft solders are used for special applications in which the properties of the lead – tin solders are inadequate. These can be based on zinc – cadmium alloys, and sometimes contain silver; they can be used at high operating temperature (>200 °C).

Lead-free tin – silver or tin – copper solders are used for soldering applications in the food industry, in the installation of copper pipework, and in the refrigeration industry.

Soft Solders for Aluminum-Based Materials. Zinc-containing solders are mainly used for soft soldering aluminum, and contain cadmium, tin, or aluminum as an additional alloying element. As aluminum is always difficult to wet owing to the formation of a very stable oxide layer, these solders are applied with special fluxes or special soldering techniques (e.g., ultrasonic soldering) [12].

4.2. Brazing Filler Metals

Heavy-Metal Brazing Filler Metals. Silver brazes have the widest industrial application of all the heavy-metal brazing alloys. See also → Silver, Silver Compounds, and Silver Alloys, Chap. 10.7.. Their operating temperatures lie between 610 and 870 °C, depending on the silver content and the other alloying elements. Alloys with higher silver content permit lower brazing temperature, which offer both technical and economic advantages. They also contain copper and zinc, and sometimes tin or cadmium. When working with cadmium- containing brazing filler metals, special precautions must be taken for safety reasons (see Chap. 8).

Table 1. Properties and uses of selected soldering and brazing alloys

Designation	Melting temperature range, °C	Typical solders (DIN designation)	Solidus temperature, °C	Liquidus temperature, °C	Main areas of application
Lead – tin soft solders (DIN 1707)	185 – 325	L-Sn60Pb	183	190	electrical industry

∗ Not standardized.

Phosphorus-containing brazing filler metals can be used to join copper to copper in air without a flux. This is used in the construction of electrical machinery, in copper pipe installation, and in other areas.

High-melting, silver-free brazing alloys are used in applications where high brazing temperature can be tolerated. Copper and copper–tin alloys are mainly applied in a furnace under a protective gas or in vacuum, but brass and "German silver" brazing alloys (CuZn and CuZnNi, respectively) are mainly applied with flux in air for bonding steel components.

Light-Metal Brazing Alloys. The most common alloy for brazing aluminum is the eutectic aluminum brazing alloy containing 12 % silicon (operating temperature: 590 °C). A rod of alloy can be used with a suitable flux for manual brazing. The industrial brazing of aluminum (e.g., for automobile radiators) is often carried out with sheet aluminum precoated with brazing alloy. The assembled parts are then brazed, with or without a flux, in special furnaces with very precise temperature control [13].

High-temperature brazing filler metals are used when the brazed joint must have a high strength at high operating temperature (ca. $\geq$ 400 °C). This is usually associated with a need for oxidation-resistance. If the brazed joints have to be highly corrosion resistant, high-temperature brazing alloys are often used.

Nickel-base brazing alloys are preferred (→ Nickel Alloys, Chap. 8., → Nickel Alloys, Chap. 9.). They contain chromium with varying amounts of boron, silicon, or phosphorus to reduce the melting range. The nickel-base brazing alloys are brittle, and hence cannot be produced in the form of ribbon or wire; they are usually supplied as powder or paste. However, some nickel-base filler metals can be produced in the form of amorphous ribbons by rapid solidification by the "melt-spin" process. During the brazing process, suitable heating can cause diffusion of boron and silicon into the substrate, resulting in ductile brazed joints of high strength [14], [15].

In addition to the nickel-base filler metals, gold- and palladium-containing brazing alloys (rarely platinum) are available in the form of wire, ribbon, or preforms. Due to their

high noble-metal content, brazing alloys of this type are relatively expensive. An example of an industrially important gold brazing alloy is Au82Ni18, which is used in the construction of engines and in aerospace applications [16]. The palladium- containing silver–copper alloys may also belong to the group of high-temperature brazing alloys, depending on their working temperature. Their most important use is the brazing of metallic substrates to metallized ceramics in power-electronic components.

Unmetallized ceramics, diamond, and glass can be brazed with special "active brazing" alloys [17]. These filler metals contain elements that promote wetting, e.g., titanium or zirconium, and can directly wet nonmetallic inorganic materials.

As well as steels and nickel-base materials, titanium alloys are now being increasingly used as materials of construction for the manufacture of highly stressed components. These materials can be brazed with grades of silver-base alloys designed for vacuum application, but also with titanium-base brazing alloys that contain elements such as copper and nickel to reduce the melting range. If brazing is performed correctly, butt joints can be made with strengths comparable to those of the base material [18].

High-temperature brazing alloys and some of the standard type are frequently used in a vacuum furnace. Vaporization of alloying elements and impurities during brazing is prevented by using brazing alloys specially designed for vacuum use. These alloys do not contain components with a high vapor pressure, and their purity specification is tighter.

5. Fluxes and Protective Atmospheres

Fluxes are organic or inorganic substances that remove oxides and other harmful layers from the surface to be joined by soldering or brazing. They thereby provide the conditions that allow wetting by the molten filler metal.

Soft-Solder Fluxes. The fluxes for soft soldering are classified according to their effectiveness in removing oxide layers from metallic surfaces. The oxides on the substrate are of varying stability; for example, the soldering of copper requires a less "aggressive" flux, while a more active flux is required for chrome steels. However, increasing activity of the flux is accompanied by increasing corrosiveness, so that the flux must be completely removed after soldering by washing with water or solvents, especially if it is of the more active type.

Typical active components of soft-solder fluxes include hydrochloric acid, zinc chloride, ammonium chloride, citric acid, organo halogen compounds, and natural and modified resins.

Brazing Fluxes. The fluxes used for brazing aluminum are classified according to the corrosive action of their residues. Hygroscopic fluxes must be scrupulously removed by washing with water after brazing due to their corrosive properties. In contrast, water-insoluble residues can be left on the brazed area provided that they do not interfere with subsequent processing, e.g., painting or plating. The active temperature range (i.e., the range within which the flux can remove the oxide layer from the surface to be brazed) is relatively narrow for both groups of fluxes used for brazing aluminum (ca. 500 – 600 °C).

In the case of heavy-metal brazing fluxes, it is necessary to work within the active temperature range of the particular flux being used. The choice of flux depends mainly on the brazing temperature, which in turn depends on the brazing alloy. As the residues from nearly all these fluxes are corrosive, they must be removed after brazing.

Copper, copper – tin, or silver can be brazed in air without fluxes if phosphorus- containing copper-based brazing alloys are used. The phosphorus has a similar effect to that of a flux.

Brazing Atmospheres. With the above-mentioned exception of phosphorus- containing, copper-based brazing alloys, flux-free brazing requires a special atmosphere such as a protective gas or vacuum (see Section 3.8). Above a certain temperature, the atmosphere decomposes the oxide layer on the surface of the workpiece and prevents it from reforming. The required temperature depends on the quality of the brazing atmosphere, and is determined by the metal – metal oxide equilibrium curves (Fig. 3). Different compositions and purities of brazing atmospheres are thus required for each brazing

alloy and base material. The brazing of low-alloy steels on a production basis can be carried out very economically in a continuous furnace, e.g., in protective gas atmospheres of incompletely combusted natural gas or propane. However, high-alloy special steels or oxygen-sensitive materials (titanium or zirconium) require very pure atmospheres with extremely low levels of oxygen and water vapor; good brazing results can normally only be obtained in high vacuum (10 to 1 mPa, i.e., 10^{-4} to 10^{-5} mbar) [19].

6. Materials of Construction Suitable for Soldering and Brazing

An important advantage of brazing as a joining technique is that it permits the bonding different types of material. For example, ceramic and steel can be very strongly bonded by using special brazing alloys and brazing processes.

Materials of construction can be divided into three main groups according to their brazability [20]:

1) Materials that can be brazed using general-purpose brazing alloys, general-purpose fluxes, and standard processes (e.g., copper and nickel alloys, iron, steels, cobalt, and noble metals)
2) Materials requiring special brazing alloys and/or special fluxes, but not special processes (aluminum, hard metals, stellite, chromium, molybdenum, tungsten, tantalum, and niobium)
3) Materials that can only be brazed with special brazing alloys and special processes (titanium, zirconium, beryllium)

Nonmetallic inorganic materials (e.g., ceramics, diamond, and graphite can be brazed with special brazing alloys (see Section 4.2) [21], [22].

The above examples also apply to soft soldering to a limited extent. Some materials of construction must be regarded as impossible to soft soldering on an industrial scale (e.g., beryllium and cemented carbides).

7. Design and Strength Properties of Soldered and Brazed Joints

Dimensioning. In capillary soldering or brazing, the molten filler metal flows into the gap by capillary attraction and solidifies, thus bonding the surfaces to be joined. Normally, the gap width should be between 0.05 mm and 0.2 mm (see Chap. 2). If materials with different thermal expansion coefficient are bonded together, care must be taken that the desired gap width exists at the soldering or brazing temperature – this may require a narrower or wider gap at room temperature.

In addition to gap size, the dimensions of the area to be joined must be established for highly stressed soldered or brazed joints. It must be ensured that brazed joints can be subjected to as much stress as the substrate material. With overlapping joints, this is the case when the length of the overlap corresponds to 3 – 6 times the wall thickness of the weaker material to be joined.

The surface area of the joint can be dimensioned according to the theory of strengths of materials. For quasistatic loads at room temperature, the tensile strength R_m should be ca. 200 N/mm^2 and the shear stress at failure τ_B ca. 100 N/mm^2. The strength of brazed joints can be considerably higher in practice, but they should be determined, if possible, by standard tests (DIN 8525).

The amount of solder or brazing alloy required to make a joint can be determined from the maximum gap volume, with an addition of ca. 30 % to allow for the formation of fillets.

Joint Design. In order to optimize soldered or brazed joints, the following rules for design should be observed:

Table 2. Tensile strength (MPa) of joints made with brazing alloys and steels measured according to DIN 8525, Part 1

Filler metal	Base material (steel)			
(DIN 8513)	St 37	St 50	St 60	Stainless
L-Ag44	390 ∗	480	520	530
L-Ag40Cd	410 ∗	530	640	520
L-CuZn40	360		420	

∗ Fracture in base material.

1) The gaps to be soldered or brazed should have parallel sides of defined width.
2) The filler metal should be located so that, on melting, it comes into immediate contact with the surfaces to be joined. In some cases, the filler metal can be placed in the gap in the form of ribbon or specially shaped pieces (preforms) prior to joining.
3) If possible, the workpieces should be arranged so that they locate automatically. A three-line press fit or a knurled press fit can be used for joining shafts or wheels.
4) It must be ensured that the flux can be displaced by the molten filler metal so that flux inclusions are avoided (Fig. 4).
5) Sudden changes in cross section should be avoided in highly stressed brazed joints.
6) Any machining marks on the surfaces to be joined should be orientated in the direction of the flow of the filler metal.

Figure 4. Prevention of flux inclusions
A) Escape of flux through a flux discharge opening; B) Brazing with preplaced shim of alloy

Joint Strength. Even at room temperature, joints made of normal soft solders usually have low strength ($<10\,N/mm^2$) due to creep [23]. Owing to their poor strength, soft-soldered joints are unsuitable for stressed structures under static load unless additional mechanical support is provided, e.g., by means of a form fit. Soft-soldered joints are thus generally used on account of their sealing or electrically conductive properties.

The tensile strength of brazed joints made with copper and copper alloys often exceeds the strength of the base material. Table 2 lists the strength of joints made in steel. The high strength values enable brazed joints to be employed for stressed structures. A decrease in strength is observed above 200 °C.

8. Safety Aspects

Safety aspects of soldering and brazing are covered by national regulations, only a few examples can be mentioned here [24], [25].

Effective ventilation of the workplace is very important to remove hazardous vapors or dusts derived from the fluxes and the solders. When using cadmium- containing solders, special safety precautions must be observed because the cadmium oxide fume produced is classified as a carcinogen. If possible, cadmium-free solders should be used.

Before using fluxes and filler metals, the safety data sheets provided by the manufacturer or supplier should be consulted for details concerning safe handling. Appropriate protective clothing and equipment should be used. For brazing, safety spectacles should be worn for protection against spurting, dazzle, and heat radiation. Further details are given in national regulations. When working with a flame, suitable precautions against injury from burns should be taken.

The safe handling of flammable gases for flame brazing and furnace brazing requires specialist knowledge, and should therefore only be carried out by trained personnel.
